Fig. 1 (Sudranski). Photograph of the right eye, made under intense focal illumination (directed from the temporal side) with the pupil widely dilated, showing the pupillary margin at P, the corneal limbus at L, and the folded iris tissue at I. S marks the site of the scar near the corneal limbus temporally and directed toward the corneal vertex. The large, bright reflex from the anterior surface of the cornea is at R. The smaller, fainter reflex from the anterior surface of the lens is at R'. The latter is seen at the same level as the cataractous markings of the anterior lens capsule, C. The far periphery of the lens appears entirely black, indicating that the anterior lens capsule is uninvolved where the lens surface, near its equator, curves sharply away from the plane of the iris. (Official U. S. Navy photograph.)

bodies (one of which was localized in or close to the sclera) were still demonstrable by the X ray. Two observations would appear to afford sufficient evidence that, in this case, the intraocular metallic foreign particle may have been actually extruded from the eyeball by transcleral migration; namely, (1) the foreign bodies roentgenographically visible were not reduced in number (even though the one at first observed within the vitreous had later disappeared), and (2) the slight disturbance of the retinal pigment in the lower temporal portion of the fundus.

Even more remarkable is the presence of grayish-white opacities of the anterior lens capsule so arranged as to reproduce, in detail, the anatomic markings of the posterior iris surface. This finding may be regarded as typical of a distinct cate-

gory of traumatic cataract. The contusion cataract of the anterior lens capsule is illustrated photographically in figure 1.

Although the iris, at its free margin, lies practically in contact with the anterior surface of the lens, yet there is a thin layer of aqueous intervening. Therefore, pressure directed upon the anterior aspect of the eyeball, however great and however sudden in origin, must, according to the laws of physics, be distributed equally throughout the globe. Because of the free communication of the anterior and posterior chambers through the pupil, it should not be possible for any pressure change within the eye to force the iris

against the lens, for the equal distribution of pressure throughout the globe would result in as great a pressure being exerted away from the lens from the posterior chamber as toward it from the anterior chamber. However, this conception of the ocular hydrodynamics fails to consider the fact that the eyeball is a structure of living tissues whose physiologic activity considerably modifies the operation of purely physical laws. In the closed space of the living eyeball, the intraocular pressure is maintained by the circulation of blood through the vascular system, the secretion of aqueous by the ciliary body (in turn dependent upon the circulation), and the drainage of aqueous through Schlemm's canal and the venous system. Sudden pressure upon the eyeball, by increasing the intraocular pressure, cuts off the arterial circulation, reduces the secretion of aqueous by the ciliary body, and forces the exit of aqueous through the drainage channels. As the aqueous drains from the anterior chamber, it is replaced by fluid from the posterior chamber which, due to slowing of the circulation through the ciliary body, is not renewed. Therefore, the iris may be forced against the lens in all or part of its pupillary circumference. In this fashion, the ring cataract of Vossius may originate. However, the physiologic modification of physical hydrodynamics within the eye would hardly appear to be adequate to account for the forceful application of the entire posterior iris surface against the anterior surface of the lens.

To provide physical conditions that would make such a movement of the iris possible, the force producing a pressure change would have to become operative after the escape of fluid from the eye had been effected. With rupture of the eyeball, the continued application of pressure would cause the aqueous to be forced from the anterior chamber through the

wound. At the same time, movement of the aqueous through the pupil into the anterior chamber would empty the posterior chamber of fluid. With the emptying of the posterior chamber, continuing pressure would then force the iris against the anterior surface of the lens at the same time draining aqueous from the anterior chamber until, if the pressure-producing force acted for a sufficiently long period of time, the cornea would eventually be applied to the anterior surface of the iris.

In the case here reported, conditions would appear to have been ideal for driving the entire iris against the lens. Rupture of the globe was accomplished by metallic particles driven through the cornea by a blast of air under pressure. How ideal these conditions were is obvious if it is assumed that the metallic particles struck the eye with the initial current of compressed air which then continued its force until turned away by the patient. Only a very short period of time was needed for such a force to empty the aqueous from the posterior chamber and drive the iris against the anterior surface of the lens. Absence of even the slightest macular damage is strong evidence favoring this theory, for it is reasonable to suppose that the force of a 50-pound stream of compressed air would surely have damaged the macula by contrecoup if the globe had not been opened at the very instant of the blast.

Contusion cataract of the anterior lens capsule, therefore, appears to originate in trauma which exerts a force continuing for a period of time after it has effected rupture of the globe. Circumstances which produce trauma of this type must be of most infrequent occurrence. Hence this variety of traumatic cataract should be a great rarity.

A STATISTICAL REVIEW OF 367 BLINDED SERVICE MEN, WORLD WAR II

FREDERIC H. THORNE, COL. (MC), U.S.A. (*Retired*)
San Antonio, Texas

The following statistics were compiled from the first 367 consecutive admissions of blinded service men of the Army to Old Farms Convalescent Hospital (Special), Avon, Connecticut. If all the World War II blinded, of which there will be approximately 1,000, were included in this review, some variations would be noted in the distribution, causes, and so forth, particularly in those cases due to disease. However, it is felt that this number of consecutive admissions will present quite an accurate picture of those blinded in the present war.

Early in World War II, two Army general hospitals were designated as centers for the medical and surgical care of the Army blinded. These hospitals were Valley Forge General Hospital, Phoenixville, Pennsylvania, and Letterman General Hospital, San Francisco, California. The blinded activity at Letterman General Hospital was transferred to Dibble General Hospital, Menlo Park, California, upon activation of the latter in 1944, while Valley Forge General Hospital continues to operate as a center for the blinded. At these two centers, concurrent with medical and surgical treatment, the blinded are given preliminary social-adjustment training consisting of Braille reading, typing, orientation, occupational

therapy, and related subjects. Upon completion of hospital treatment, the blinded are transferred to the advanced social-adjustment training center for the blinded at Old Farms Convalescent Hospital (Special), Avon, Connecticut, which was activated June 14, 1944.

The advanced social-adjustment training consists of a continuation of the adjustment begun in the two blinded centers referred to, and, in addition, there are available approximately 50 subjects and try-out jobs from which the trainee may select as many as he desires or is capable of pursuing. Among these are wood working, machine-shop work, factory jobs, counseling, guidance, business management, vending-stand operation, agriculture, book-binding, music, and similar occupations. Upon completion of advanced social adjustment, which requires approximately 18 weeks, the blinded man is discharged from the service and returned to his home.

DEFINITION OF BLINDNESS

A service man is classified as blinded or industrially blinded when central vision in the better eye is reduced to 20/200 and is not correctable, or when peripheral vision is reduced to 20 degrees or less

even though central vision is better than 20/200.

Low vision. An individual classified as blinded is referred to as having low vision when, in the better eye, vision ranges between moving objects and 2/200. Those having light perception only are, for practicable purposes, classified with the totally blinded.

Useful vision. An individual classified as blinded is referred to as having useful vision when, in the better eye, vision ranges from 3/200 to 20/200, whether it be central, peripheral, or both. In general, it is considered that individuals falling in this group can engage in various types of occupations in a manner approaching the sighted, and travel about the country without an escort. Their efficiency in this respect naturally increases in proportion as vision nears 20/200.

PLACES WHERE BLINDNESS WAS INCURRED

In so far as this report is concerned the European Theater of Operations includes England, Iceland, Greenland, France, Germany, Holland, and Belgium. The Mediterranean Theater includes North Africa, Italy, and the Middle East. The Pacific Theater includes all areas in which the Japanese were engaged in action, and the Zone of the Interior refers to the continental limits of the United States.

Blinded, residual of enemy action. Of the 367 blinded considered in this report the following percentages occurred as the result of enemy action:

European Theater	162 (44.14%)
Mediterranean Theater	46 (12.53%)
Pacific Theater	26 (7.08%)
Total	234 (63.76%)

Enemy agents through which blindness was incurred were as follows:

Booby-trap explosion	9
Bullet, machine gun, and rifle	32
Bazooka-shell explosion	5
Concussion, exploding shells, no external injuries	2
Flack and gun fire from enemy plane	5
Hand- and rifle-grenade explosion	13
Land mine explosion	41
Mortar-shell explosion	28
Shrapnel	24
Shell fragments, type of shells unknown ..	74
V-2-bomb fragments	1
Total	234

Blinded, residual of accident. Of the cases of accidental blindness, 37 can be justly classified as incidental to training. Accidental blindness was incurred in the various theaters as follows:

European Theater	14 (3.81%)
Mediterranean Theater	7 (1.91%)
Pacific Theater	11 (2.99%)
Zone of the Interior	36 (9.80%)
Total	68 (18.51%)

The following types of accidents resulted in blindness:

Airplane crash	1
Ammunition explosion (shells, cartridges) ..	8
Booby-trap explosion	4
Blasting-cap explosion	3
Dynamite explosion (catching fish for mess)	4
Dynamite explosion	4
Detonator-cap explosion	2
Gasoline fumes (high-octane gas, containing lead)	2
Gun shot	6
Grenade explosion	3
Knife wound, opening can	1
Kicked in face by mule	1
Land-mine explosion	3
Motor-vehicle accident	3
Methyl alcohol, ingestion of	14
Retinitis, solar	1
Struck in face with stick	1
Struck in eye with wrench	1
Struck in eye with garden hose	1
Struck in face with bottle	1
Struck by lightning	1
TNT explosion	3
Total	68

Blinded, residual of disease. Blindness as a result of disease occurred in:

European Theater	10 (2.72%)
Mediterranean Theater	4 (1.09%)

Pacific Theater	7 (1.91%)
Zone of the Interior	44 (11.98%)
Total	65 (17.70%)

Diseases through which blindness was incurred were as follows:

Atrophy of the optic nerve, cause obscure	14
Atrophy of the optic nerve, following try- parsamide therapy	1
Atrophy of the optic nerve, residual of brain tumor	1
Atrophy of the optic nerve, residual of encephalomyelitis following vaccinia	1
Atrophy of the optic nerve, residual of retrobulbar neuritis following spinal an- esthesia	1
Atrophy of the optic nerve, residual of epidemic cerebro-spinal meningitis	2
Atrophy of the optic nerve, residual of beriberi contracted in Japanese prison camp	4
Choroido-retinitis, syphilitic	1
Choroido-retinitis, cause obscure	6
Degeneration, macular	9
Gun-shot wound, self-inflicted	1
Keratitis, interstitial	1
Neuritis, retrobulbar, cause obscure	7
Retinitis, hemorrhagic	2
Retinitis, hemorrhagic (Eales's disease) ..	2
Retinitis proliferans	1
Retinitis pigmentosa	6
Sclerosis, multiple	2
Thrombosis, cilioretinal artery	1
Uveitis	1
Total	65

Eleven cases of blindness as the result of enemy action were due to occipital-lobe injuries without complicating injuries to the optic nerves or globes.

In the case of blindness due to injury incident to opening a can with a knife, the patient had, at the time of injury, a macular degeneration of the other eye with vision reduced to counting fingers at 12 inches. The injured eye was enucleated.

In one case of blindness due to gun-shot wound of the eye, the patient had undergone an enucleation of the other eye prior to the accident.

Chart 1 (Thorne). Showing whether blindness was due to enemy action, accident, or disease.

The patient who had been blinded by a blow in the eye with stick had an amblyopia ex anopsia of the other, with vision reduced to 2/200.

the eye by a mule had an amblyopia ex anopsia of the other, with vision reduced to 4/200.
In the case of blindness caused by

Chart 2 (Thorne). Degree of blindness encountered in the 367 cases considered.

The patient who was blinded by a blow in the eye with a garden hose had an amblyopia ex anopsia of the other, with vision reduced to 20/200.

thrombosis of the cilioretinal artery, the patient had undergone, prior to onset, an enucleation of the other eye.

The patient blinded by being kicked in

Two cases of blindness caused by concussion induced by exploding shells pre-

sented bilateral macular degeneration with normal peripheral vision as to extent.

The patient who was blinded by being struck by lightning presented bilateral optic-nerve atrophy as a residual.

In the case of blindness due to a blow in the eyes with a bottle, one eye had to be enucleated and a massive detachment of the retina occurred in the other; vision was reduced to light perception.

The patient whose blindness was due to a blow in the eye with a wrench had a high myopia of the other eye with vision reduced to 4/200.

One case of blindness which occurred in the Pacific Theater was due to a self-inflicted gun-shot wound of the orbits during a period of acute mental depression.

Of the 367 patients considered, 47 (12.80 percent) had both eyes enucleated, one had both eyes eviscerated, and 147 or 40.05 percent had one eye enucleated. Binocular phthisis bulbi was found in 18 (or 4.90 percent), and monocular phthisis in 66 (or 17.98 percent).

A more detailed explanation of chart 2 follows:

Columns A and A' give data on 254 blinded or industrially blinded service men, A representing one eye and A' the other of the same individuals. A indicates that the 254 (69.20 percent) were totally blinded in one eye, while A' indicates that 121 (32.97 percent) were totally blinded in the other eye as well. Of the remaining 133 in the A' column, 76 (20.79 percent) retained light perception; 29 (7.71 percent) retained vision ranging from moving objects to 2/200; 16 (4.35 percent) retained vision ranging from 3/200 to 10/200; 11 (2.99 percent) retained vision ranging from 11/200 to 20/200, while 1 (.27 percent) retained vision better than 20/200 but with peripheral vision reduced to 20 degrees or less.

Columns B and B' give data on 29 industrially blinded service men, B representing one eye and B' the other of the same individuals. B indicates that 29 (7.90 percent) represented retained light perception in one eye while B' indicates that 13 (3.81 percent) of these retained only light perception in the other eye as well. Of the remaining 16 in column B', 8 (2.17 percent) retained vision ranging from moving objects to 2/200; 3 (.81 percent) retained vision ranging from 3/200 to 10/200; while 5 (1.36 percent) retained vision ranging from 11/200 to 20/200.

Columns C and C' give data on 47 industrially blinded service men, C representing one eye and C' the other of the same individuals. C indicates that the 47 (12.80 percent) retained vision ranging from moving objects to 2/200 in one eye, while C' indicates that 34 (9.26 percent) retained the same range of vision in the other eye as well. Of the remaining 13 in column C', 9 (2.45 percent) retained vision ranging from 3/200 to 10/200, and 4 (1.09 percent) retained vision ranging from 11/200 to 20/200.

Columns D and D' represent 22 industrially blinded service men, D representing one eye and D' the other of the same individuals. D indicates that the 22 (5.99 percent) represented retained vision ranging from 3/200 to 10/200 in one eye, while D' indicates that 17 (4.63 percent) of these retained the same range of vision in the other eye as well.

Of the remaining 5 (1.36 percent) in the D' column, all retained vision ranging from 11/200 to 20/200.

Columns E and E' represent five industrially blinded service men, E representing one eye and E' the other of the same individuals. E and E' indicate that the 5 (1.36 percent) represented retained vision in both eyes ranging from 11/200 to 20/200.

Columns F and F' represent 10 industrially blinded service men, F representing one eye and F' the other of the same individuals. F and F' indicate that the 10 (2.72 percent) represented retained central vision better than 20/200 in both

202 consecutive admissions, this being the number of men who had completed training and were separated from the service at the time this report was prepared.

The following standards were used to evaluate an individual's response to train-

Chart 3 (Thorne). Ages of 367 service men blinded in World War II.

eyes, but with peripheral vision reduced to 20 degrees or less.

In chart 3, it will be noted that of the 367 service men who were blinded 288 (78.47 percent) were below 30 years of age.

RESPONSE TO TRAINING

This portion of the report, which is concerned with training, considers only

ing: (1) Ability to orient well. (2) Determination to accept a minimum of assistance. (3) Eagerness for activity, both social and vocational. (4) Control of unwholesome antisocial habits. (5) Genuine self-confidence in capabilities and self-assurance in ability to hold a job. (6) Insight into limitations and potentialities. (7) Ability to get along with others in the community.

In rating individuals according to these standards, a seven-point score was used: Superior, excellent, very satisfactory, satisfactory, unsatisfactory, unadjustable, and incorrigible.

It will be noted in chart 4 that of the 202 blinded men whose training was completed, 160 (79.37 percent) were given a rating of satisfactory or better in respect to the results of training for rehabilitation.

A rating of unsatisfactory was given when it was felt that the blinded man did not quite measure up to the standard established and could not be considered as adjusted to his blindness. However, it was considered possible, and in some cases quite likely, that a satisfactory adjustment would eventually be made.

Of those given the grade of unsatisfactory, defects such as the following were frequently found by the psychologist: "Confused and fearful, poor home environment, poor background, irresponsible, immature, and chronic alcoholism." The average score attained by this group in the Army General Classification Test was 86.4, the highest score attained being 124 and the lowest 54. Two trainees in this group attained the score of 124. One of these had sustained a severe brain injury and was disturbed, fearful, and anxious. The other was immature, confused, and unrealistic. The trainee who attained the score of 54 was unstable, irresponsible, and had a poor home background. The average score attained in the Wechsler-Bellevue Test was 102, the highest score being 124 and the lowest 73.

The rating of unadjustable was given when the blinded man was considered to be not adjusted, and further, not adjustable nor trainable. Mental defectives and those severely disturbed emotionally were placed in this category.

Of those given the grade of unadjustable, defects such as the following were

frequently found by the psychologist: "Rejects blindness, mental defective, severe brain injury, and psychoneurotic." The average score attained by this group in the Army General Classification Test was 65.7, the highest score being 95 and the lowest 39. The trainee whose score was 95 was a hypochondriac, was fearful

Chart 4 (Thorne). Ratings of 202 blinded service men with respect to training for rehabilitation.

and dependent; and the trainee who attained the score of 39 was mentally defective and a psychoneurotic. The average score attained by this group in the Wechsler-Bellevue Test was 84.2, the highest score being 104 and the lowest 62.

The rating of incorrigible was given when the blinded man displayed antisocial behavior patterns or serious alcoholism.

Of those given the rating of incorrigible, defects such as the following were commonly found by the psychologist:

“Psychopathic, psychoneurotic, emotionally disturbed, alcoholism, and delinquent.” The average score attained by this group in the Army General Classification Test was 86.5, the highest score being 98 and the lowest 72. The trainee who attained the score of 98 was a delinquent, was psychopathic, and a chronic alcoholic; and the trainee who attained the score of 72 was a chronic alcoholic. The average score attained by this group in the Wechsler-Bellevue Test was 102.1, the highest score being 120 and the lowest 95.

SUMMARY

Number of blinded upon which report is based	367
Blinded, result of enemy action	234 (63.76%)
Blinded, causes other than	

enemy action (accident and disease)	133 (36.21%)
Totally blinded and retaining light perception only	210 (57.22%)
Low vision retained (vision of little or no value)	71 (19.34%)
Useful vision	86 (23.42%)
Both eyes enucleated or eviscerated	47 (12.80%)
One eye enucleated	147 (40.05%)
Phthisis bulbi, both eyes	18 (4.90%)
Phthisis bulbi, one eye	66 (17.98%)

Number of blinded below 30 years of age	288 (78.47%)
---	--------------

Percentage of blinded who made a satisfactory or better adjustment ..	79.37%
Percentage of blinded who made an unsatisfactory adjustment	12.25%
Percentage of blinded considered as unadjustable	4.41%

NOTES, CASES, INSTRUMENTS

OPERATIVE PROCEDURE FOR SUBLUXATED LENS

WILLIAM M. COCKRUM, M.D., AND
HOWARD C. SLAUGHTER, M.D.
Evansville, Indiana

The subluxated lens, or tremulous lens, according to Duke-Elder,¹ occurs when the suspensory apparatus is weakened so that the lens becomes tremulous, or subluxated, but remains within the pupillary aperture. This is to say that some of the suspensory ligament does not remain intact. The usual surgical procedure for the removal of such lenses is by spoon or loop extraction or, if the patient is younger, by discission. Dutt² discussed the nonviolent delivery of the subluxated lens by the lever-action intracapsular route. By this method, the lens is removed from the anterior chamber after iridectomy by rotating it through the corneal wound, using the attached zonule as the fulcrum and providing pressure on the globe below. Knapp's³ paper on the operative treatment of congenital subluxated lens reviews the types of operations from which to choose. The first was an iridectomy to give a clear zone in the aphakic area through which to see. The second is discission, which is very difficult because the lens eludes the end of the knife; there is no tension on the capsule; and the opening is small. Moreover, the incision does not remain open, and several operative procedures are usually necessary. Knapp states that needling should be done in adolescence only. The third choice is removal of the lens by spoon or loop extraction. The indications for operation are cyclitis, glaucoma, or poor vision.

The procedure under discussion consists of the usual keratome incision with McLean suture. The incision is enlarged

with the scissors. Iridectomy is then performed at the 12-o'clock position with the use of a blunt iris hook to engage the iridic margin. The iris is drawn up into the incision and the iridectomy performed. During the entire operative procedure, it is necessary that the assistant hold the lids away from the globe. After the iridectomy is performed, an Arruga forceps is used to enter the anterior chamber; the upper margin of the subluxated lens is grasped, and the lens withdrawn from the anterior chamber by the intracapsular route.

The causes for subluxation of the lens can be congenital, traumatic, and consecutive or spontaneous. The findings are a deep anterior chamber, iridodonesis. The convex edge of the lens can usually be seen in some part of the pupillary aperture. Monocular diplopia may be present.

REPORT OF CASE

A white man, single, aged 37 years, was first seen in the office on December 30, 1944. He said that he had had poor vision in his left eye for a number of years and, about four weeks previous to this date, the visual acuity in his right eye suddenly diminished. The eye had been moderately red since that date. The patient did not report loss of vision in his left eye. He did not have monocular diplopia. He had not suffered trauma but had been doing heavy labor, part of which consisted of carrying 100-lb. sacks on his shoulders. This, we think, could traumatize a congenitally weak suspensory apparatus sufficiently to allow the lens to subluxate.

On examination, it was found that this man had a bilateral dislocation of both lenses. The anterior chamber was deep and iridodonesis was present. The superior margin of the lens could be seen in

each eye, covering about two thirds of the pupillary aperture. The pupil of the right eye was widely dilated and fixed to light, but the left eye was normal in size and reacted to light. There was a mild ciliary congestion of the right eye. The tension in the right eye was 15 mm. Hg (Schiotz); in the left eye 13 mm. The fundus, viewed through the aphakic portion, appeared normal in both eyes.

The patient was not wearing glasses. His vision, with squinting, was 20/300 in the right eye; 20/200, in the left. Atropine, to be used twice a day in the right eye, was prescribed, and the patient was advised to use hot packs and return on January 2d for the surgical removal of the dislocated lenses.

Family history revealed that this man's maternal grandmother had undergone an operation for dislocated lenses 50 years ago. His mother and two of his uncles had dislocated lenses. The mother had an operation on both eyes, one of them successful, about 40 years ago. One of the uncles had also been operated upon successfully about 40 years ago. The second uncle was under regular observation by a physician. The patient had six brothers and one sister. Two of the brothers had dislocated lenses but refused operative procedures, for they were comfortable and had good vision with glasses. A family characteristic was height of about 6 ft.

Physical examination revealed a tall, thin man, weight 145 lbs. (65.9 kg.), height 73 in. (185 cm.), with a long, thin trunk and arms of greater than normal length. This patient fits the description of Marfan's syndrome.

On January 2d, the lens of the left eye was extracted under local anesthesia. During the operative procedure, the lens tilted into the anterior chamber and was very easily grasped with the Arruga for-

ceps and removed. It was not necessary to assist the removal of the lens in any other way. The position of the lens was viewed through the cornea, not by direct vision. A bead of vitreous showed in the wound at the conclusion of the operation. However, it was not cut off, and the eye was bandaged with a dry dressing. The dressing was changed on the second postoperative day. The prolapse of vitreous was not marked, but had increased somewhat and, on the third postoperative day, the protruding vitreous was touched with a heated muscle hook.

The patient was very anxious to have the lens removed from his right eye. On January 8th, a similar operation was performed on the right eye without prolapse of vitreous. A McLean suture sealed the wound satisfactorily. The postoperative course was uneventful, and the patient was discharged from the hospital on January 13th, with some gaping of the wound of the left eye at the point of the prolapse of the vitreous. He was not seen again until January 22d, when vision was: R.E. with a +13.00D. sph., 20/50; L.E., with a +13.75D. sph. \ominus -2.75D. cyl. ax. 60°, 20/40. He still had some irritation of the right eye. He was given atropine; and also typhoid antigen H (20 million organisms) intravenously.

He was then seen at weekly intervals, and the right eye gradually cleared. He wore temporary lenses in the form of spheres until April 13th, when permanent lenses were prescribed. Vision was: R.E., with a +14.25D. sph. \ominus -1.25D. cyl. ax. 110°, 20/40; L.E., with a +14.75D. sph. \ominus -1.25D. cyl. ax. 45°, 20/30. An addition of +2.75 D. sph. was given for close work. Binocular vision, was 20/25-2. The patient stated that he saw better than he ever had in his life.

UNUSUAL COMPLICATION OF SPHENOPALATINE BLOCK

VICTOR GOODSIDE, CAPT. (MC), A.U.S.
AND SAMSON WEINGEIST, CAPT.
(MC), A.U.S.

Fort Bragg, North Carolina

The present report is concerned with a complication of sphenopalatine, or maxillary-nerve block, evidently not of frequent occurrence. In performing this procedure, it has been customary in our experience to enter the needle into the palatine foramen in an upward direction, passing it through the pterygopalatine canal into the pterygopalatine fossa to a depth of about 3 cm. From 2 to 2½ c.c. of a 1-percent solution of novocaine is usually injected. The anesthesia produced is useful in dental surgery; in nasal surgery, both alone and as an adjunct to topical application of cocaine; in the treatment of sphenopalatine neuralgia; and, finally, in the treatment of ocular pain. It is possible for the needle, if carried too far, to pass through the pterygopalatine fossa into the inferior orbital fissure. The effects obtained when this occurs will depend on the precise site of deposition of the anesthetic agent. Two cases are here presented in which temporary paralysis of the external rectus muscle was produced by the injection described.

Case 1. Novocaine (2½ c.c. of a 1-percent solution) was injected on the left side

in the manner described as preliminary to dental surgery. Five minutes later, the patient complained of double vision. On examination, 15 minutes later, he was found to have complete paralysis of the external rectus muscle on the side injected. There was complete corneal anesthesia. The pupil was slightly irregular, somewhat larger than that of the fellow eye, and slightly sluggish in response to light and accommodation. Ocular examination was otherwise completely negative. Two hours later, the diplopia was no longer in evidence; ocular movements were normal in all directions of gaze; corneal sensitivity had returned; and the pupils were equal and regular and responded actively to light and accommodation.

Case 2. A patient received an injection of 1 c.c. of a 1-percent solution of novocaine and of 1 c.c. absolute alcohol into the pterygopalatine fossa in treatment for sphenopalatine neuralgia. Almost immediately, the patient complained of double vision. Examination revealed complete paralysis of the external rectus muscle. Pupils were equal and regular and reacted to light and accommodation. Corneal reflexes were retained. The paralysis of the external rectus receded gradually over a period of two days. The patient was returned to duty nine days later without complaint.

Regional Station Hospital.

RECURRENT DETACHMENT OF THE CHOROID FOLLOWING TREPHINING OPERATION*

JAMES W. SMITH, M.D.

New York

In 1868, Herman Knapp diagnosed sarcoma of the choroid in an eye following cataract extraction which, on section, proved to be a choroidal detachment. Similar reports by competent ophthalmologists have appeared as recently as 1934. Operations or injuries that induce marked reduction in intraocular pressure have long been recognized as occasionally giving rise to choroidal separation. This separation was looked upon as a transient phenomenon that disappeared in several days following wound closure and the establishment of normal intraocular pressure.

When Elliot's trephining operation for chronic noninflammatory glaucoma gained acceptance, observers reported that choroidal separation not only occurred frequently, but that the detachments often were of longer duration. Prior to the use of corneoscleral sutures, few observers had the courage to examine fundi earlier than one week after cataract extraction, whereas ophthalmoscopy sooner after trephination was entirely safe. O'Brien¹ found transient separation of the choroid in 93 percent of his cataract-extraction series. Although Elliot admitted reluctantly that the complication occurred in about 3.5 percent of trephining operations, the reports of Bothman and Blaess,² Rycroft,³ and Rubert⁴ showed an incidence varying from 14 to 50 percent.

According to Fuchs, a rent in the perichoroidal space followed by transudation

of fluid from the choroidal vessels produces the detachment which disappears when the leaking surgical section heals firmly. Spaeth and DeLong⁵ believe that choroidal detachment "may be due to massive edema, a disturbance of the perichoroid or hemorrhagic choroiditis or a combination of the three conditions." They suggest "massive perichoroidal edema" as a more correct designation for postoperative and posttraumatic conditions not essentially hemorrhagic.

It is generally accepted that most postoperative detachments of the choroid disappear completely within three to seven days. However, many cases are reported of anterior chambers that remained open for six weeks or even six months with persistence of the choroidal separation. Stress has not been laid upon the danger of such a prolonged complication. Failure of the anterior chamber to re-form creates an abnormal situation giving rise to low-grade uveitis, synechia in the anterior angle, and lens-capsule and cortex opacities. Persistent detachment of the choroid is delineated by pigment granules and streaks seen ophthalmoscopically, and later by actual degenerative changes in the choroid and retina. Secondary hemorrhage and absolute glaucoma may develop, causing blindness and necessitating enucleation.

In view of these possibilities, concern must be expressed at the therapeutic suggestions appearing in ophthalmic textbooks. For treatment of choroidal separation Berens advises "keeping the patient in bed;" Elliot recommends "getting the patient out of bed;" and Parsons dismisses the subject by stating that "most patients get well without treatment." Verhoeff and others recommend scleral puncture to effect reposition by withdrawing serous fluid in the perichoroidal space. The procedures having the soundest surgical basis are cauterization of the tre-

phined bleb or covering it with a flap of conjunctiva or a strip of superior-rectus tendon. Disagreement exists regarding the safe period before effecting closure of a fistulizing wound. Rycroft believes that a trephine leak should be sealed off after seven days, whereas Duke-Elder suggests repair if the choroidal detachment has persisted for three months!

A warning should be sounded against these extreme views. The danger of prolonged bed rest, particularly in aged patients, cannot be overemphasized. In addition, the upright position, by gravity, decreases the amount of fluid lost through the open wound. Intervention seven days postoperatively is unwarranted. I know of one case wherein premature and excessive cauterization precipitated a fresh attack of glaucoma. Excessive delay for three months can lead only to the complications mentioned above. Choroidal separation and failure of the anterior chamber to re-form two weeks after trephination must be regarded seriously. Mild cauterization of the conjunctival wound edges is indicated and may be repeated every third day if necessary. When this treatment is not effective within two weeks, the trephine bleb should be covered with a flap of conjunctiva or superior-rectus tendon.

CASE REPORT

A 1½-mm. trephination of the right eye (May 4, 1943) was effective in reducing intraocular pressure for six weeks and, despite daily use of miotics, the pressure was controlled for only one year. On June 9, 1944, a 2-mm. trephining operation was performed 4 mm. temporal to the former site. The globe was too soft for accurate ophthalmoscopy until the sixth day, when detachment of the choroid was observed in the inferior portion rising almost to the inferior edge of the optic nerve. Two days

later the anterior chamber re-formed, the choroid appeared to be replaced, the patient left the hospital, and vision improved from perception of fingers to 20/100. After six days, detachment again occurred which lasted 48 hours. On July 4th, excessive tearing was present, followed by visual veiling and distortion which persisted for 12 hours.

The fourth detachment on July 21st cleared in two days, with recovery of vision to 20/50+2. Two transient spells of tearing, veiling, and distortion were observed by the patient in August. The fifth and last detachment was seen on September 11th, three months after the operation.

Vision in the left eye with glaucomatous optic-nerve atrophy was 3/200 in a 15-degree temporal sector only. Some apprehension was felt regarding the ultimate outcome in the patient's only useful eye. Procedures considered were cauterization of the bleb and Magitot's⁶ operation for covering trephine opening with a strip of superior-rectus tendon. The possibility of wound closure with return of glaucoma suggested that conservatism would be the wiser choice. Treatment, therefore, was limited to continual *ad maximum* dilatation of the pupil of the right eye, using 1-percent atropine followed by paredrine three times daily. The outstanding clinical finding observed since the operation was the appearance of a fixed arc of pigment granules corresponding to the summit of the choroidal detachment. The nasal half of this pigment line disappeared after two months, and at present only several fine pigment dots are noted in the choroid 2½ disc diameters inferior to the optic nerve, with evidence of thinning of the choroid due to atrophy. Hypotony was present for four months, when a small bleb appeared over the site of trephination and the tension rose to 20 mm. Hg

(Schiøtz), which has been maintained to date. The field of vision is fuller at present than it was preoperatively, and there is a 15-degree contracture superonasally and one 20 degrees superotemporally. Three diopters of myopia⁷ have developed since operation, and with full correction the vision is 20/50— due to the sclerosis of the lens nucleus, which was noted

before operation. At first dressing an interesting clinical finding was the almost complete loss of the normal upper-lid convexity. This defect has persisted to a lesser degree and is probably associated with a loss of scleral curvature about the zone of operation.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

October 18, 1945

DR. WARREN S. REESE, *chairman*

NEUROFIBROMATOSIS IN THREE CONSECUTIVE GENERATIONS

DR. EDITH HARVEY (by invitation) presented the case of a girl, 5 years of age, who entered the clinic, with a history of gradual protrusion and deviation downward of her left eyeball. She was an intelligent, healthy child, having had none of the usual childhood diseases except occasional colds. A tonsillectomy had been performed the previous year.

On examination, there was an exophthalmos of the left eye measuring 3 mm., with the visual axis directed downward 30° and temporally 5°, while the visual axis of the normal eye was directed straight forward. Ocular rotations were fairly good in all fields except that of the superior rectus, in which there was definite limitation. Visual acuity was 20/30 in the normal eye and 1/200 in the exophthalmic eye. There was a definite unilateral papilledema in the left eye. She had café-au-lait pigment spots on her chest and abdomen, but no subcutaneous neurofibromata.

Blood count and urinalysis were normal, as were the serum, calcium, and phosphorus determinations.

Roentgenographic studies of the orbit showed no bone involvement, except some slight enlargement of the optic foramen on the involved side. The sphenoidal ridges were normal, and the bones of the skull showed no abnormalities. There

was no evidence of calcification. Roentgenographic studies of the sinuses were normal.

The patient was operated upon by Dr. E. B. Spaeth. A neurofibroma was found encircling the entire intraorbital portion of the optic nerve from its exit from the eyeball to the optic foramen. The eyeball and optic nerve up to the foramen were removed. The tumor mass, which was about 9 mm. in diameter along the entire length of the nerve, seemed to be constricted to the normal size of the nerve at the optic foramen, and it is to be hoped that it did not involve the intracranial portion of the nerve.

No other tumor masses were palpable in the orbit.

Microscopic sections of the enucleated eyeball and optic nerve showed an intact, undamaged optic nerve with a pure fibroma, containing no nerve fibers, surrounding it. There was, in addition, edematous infiltration of the nerve heads. The slides of these sections were discussed later in detail by Dr. DeLong, under whose direction they were made and carefully studied.

The mother of the child had multiple, cutaneous neurofibromata, most numerous over her back, but scattered also on her abdomen, neck, and extremities. Many had been present since birth; others appeared at puberty. She had a few café-au-lait spots on her abdomen. One of the tumor masses on her arm was removed, and the microscopic diagnosis was neurofibroma. When a similar tumor had been removed some years previously, the same microscopic report had been given.

The child's grandfather, on the maternal side, had died at the Presbyterian

Hospital. He had had a suboccipital craniotomy for neurofibromatosis of the middle and posterior fossae. Necropsy findings included: generalized neurofibromatosis, gastric subserous neurofibroma, and a cervical perineural fibrosarcoma.

The antecedent relatives lived in Norway, and the only history obtainable was the recollection of the child's mother that she had heard that her own grandmother, on the paternal side, had had several nodular masses on her face. Whether these were neurofibromata is, of course, impossible to determine.

The brother of the child, and the sisters and brothers of the mother, have no known abnormalities suggestive of neurofibromatosis.

Dr. Harvey pointed out that neurofibromatosis is an hereditary and sometimes familial condition characterized by skin lesions and tumors on nerves. These lesions she discussed in detail, and presented a brief résumé of the general symptoms.

She also stated that this disease is congenital, showing Mendelian dominance in successive generations, although occasionally one is skipped. There is no sign of sex-linked inheritance.

There seems to be a congenital defect which exists in the nerve-sheath tissue, resulting in a hyperplasia of the nerve-sheath connective tissue, the cells being adult in type and not embryonic. The stimulus for hyperplasia is present from birth. New tumor masses may appear at puberty, pregnancy, or with intercurrent infections. They are not stimulated by local trauma.

The origin of these tumors has been a matter of controversy which is still not settled. Von Recklinghausen believed that the tumors were mesoblastic in origin, arising from the endoneurium. Verocay considered them as ectodermal derived from the cells of the sheath of Schwann.

According to Penfield and Young they are the result of a connective-tissue reaction about the fibers of the nerves, and show both nerve fibers and connective-tissue elements, although the differentiated fibroblast, and not glial cell, is the typical cell. Whether cells of the sheath of Schwann are specialized glial cells or not is still a disputed question.

Sarcomatous changes have frequently occurred in neurofibromatosis. Operative removal of a neurofibroma may be followed by the recurrence of a benign neurofibroma. On the other hand, sarcomatous transformation may occur at the site of removal or in a distant preëxisting fibromatosis nodule. Metastasis is relatively infrequent, when a benign neurofibroma becomes sarcomatous; instead it is followed by transformation into sarcoma of a neurofibroma in another part of the body.

Discussion. Dr. Perce Delong said that this multiple tumorous syndrome is a disease of congenital origin characterized by cutaneous pigmentation and multiple tumors of cranial and peripheral nerves. The growths in Von Recklinghausen's disease are not true neuromas, which must consist of both nerve tissues and nerve cells, hence the term neurofibromatosis.

Penfield and Young, in describing the involvement of the nerve trunks, meninges, and central nervous system, state that there is found a definite hyperplastic reaction of the cells peculiar to these tissues, indicating that there must have been an irritant or stimulating influence exerted on these tissues, causing hyperplasia, which is followed by true neoplastic growth of these cells.

This specimen does not differ from those reported. The clinical, ocular signs are secondary. These are: exophthalmos, due to pressure from behind; choked disc, due to pressure; degeneration; and optic atrophy. Van der Hoeve is the only one

who reported an ocular manifestation involving the retina.

Pathologic change in this case showed the tunics of the globe to be normal with the exception of one ciliary nerve which presented some edema of the nerve with a thickening of its sheaths. There was also an early papilledema of the nerve head.

The optic nerve presents marked edema of the nerve and definite fibrosis of the sheaths. The hyperplasia is most marked in the region of the arachnoid, giving the nerve the appearance of being about twice its size. Microscopically, no cellular elements are present, but marked hyperplasia and fibrosis of the nerve sheaths.

Dr. E. B. Spaeth said that he again wished to call special attention to the matter of development of sarcoma in neurofibromatosis. He had recently seen two additional cases. The first patient presented before this group about two years ago with neurofibromatosis in the upper division of the 5th nerve, now had developed sarcomatous changes accompanied by severe hemorrhages.

The second patient had a neurogenic sarcoma which seemed to arise in an otherwise benign neurofibroma of the orbit.

The astonishing feature in the cases presented by Dr. Harvey was that one will probably never see three more dissimilar instances of a common hereditary process. In the first case, that of the grandfather, there was a neurogenic sarcoma (sarcomatous changes from neurofibromatosis). In the second case, that of the mother, the lesions were confined purely to the skin. In the third case, the child's, there was a neurofibroma of the optic nerve, itself.

Dr. Francis H. Adler asked Dr. Harvey whether this tumor did not originate in the sheath of the nerve, not the nerve fibers. He added that he would like to

point out that the theory that these tumors start in the neurilemmal sheath must be wrong, at least in the case of the optic nerve, because the optic nerve fibers, like the fiber tracts of the brain, have no neurilemmal sheath. It is not a true sensory nerve.

Dr. Edith Harvey replied that it is now generally believed that neurofibromas arise from the connective-tissue sheaths of the nerves, and not from the neurilemma; that is, they are mesodermal in origin.

A POSSIBLE EARLY CASE OF OCULAR PEMPHIGUS

DR. JOSEPH V. KLAUDER (by invitation) and DR. ALFRED COWAN presented the case of a white woman, aged 29 years, who, since February, 1944, had had recurring erosive areas on the buccal mucosa, the lips, under the tongue, and on the floor of the mouth. These areas disappeared and reappeared at intervals of a few weeks to a few months. When lesions appeared on the lips, she observed that the initial manifestation was a blister which soon ruptured, leaving a crusted surface.

In July, 1945, when first seen, she had a cutaneous outbreak. This was the first time such lesions appeared. On each elbow there was a bleb which was partially collapsed. The skin around the bleb was normal. There was a similar lesion near the external canthus of the right eye. The lower lip was covered with a crust, when this was removed, a moist bleeding surface was seen. On each buccal mucosa, there were marginated superficial ulcerations the surfaces of which were covered with a yellowish membrane. There were no vesicles on the lips nor in the mouth.

In August, during the time lesions were in the mouth and on the skin, both eyes became inflamed. Examination showed intense infection of the palpebral and

bulbar conjunctiva. There was a distinct membrane on the tarsal conjunctiva of the lower lids and on the bulbar conjunctiva on the temporal side. Both upper lids were similarly affected. Examination by slit microscopy showed both corneas clear, there were no vesicles, the aqueous was clear, the iris intact, and the lens unaffected.

Infection of the conjunctiva gradually subsided, and the membrane on the conjunctiva in both eyes disappeared. In the latter part of September, there was a recurrence of conjunctival redness, membrane formation on upper and lower lids, and moderate swelling of the upper lid with free discharge. No vesicles were seen in either cornea.

The patient had no fever and no constitutional symptoms. Sulfadiazine was given internally, and sulfathiazole ointment was used in the eyes. Fowler's solution was administered by mouth in doses varying from 3 to 6 drops, three times daily. Repeated smallpox vaccinations were performed. A strict, saltless diet was instituted.

Ocular inflammation again subsided. The patient now presented only erosive areas on the inner surfaces of the lips and on the buccal mucosa.

Discussion. Dr. George S. Dublin said that it has been his good fortune to be able to see this case from its beginning. When first seen, there was noted a severe inflammation of the conjunctiva. A distinct membrane was present on the tarsal conjunctiva of the lids. This membrane, yellowish in color, appeared to be on the surface of the conjunctival epithelium and did not appear to involve the deeper layers. He had tried to remove part of the membrane but was unsuccessful. About two or three days later, a membrane appeared on the bulbar conjunctiva both temporally and nasally, paralleling the limbal border, in one eye extending to the

outer canthus. In addition, there was a profuse ropy discharge.

Dr. Klauder's earlier findings of vesicular formation in the skin together with a stomatitis pointed to a possible pemphigus. Mild lotions were prescribed, and the condition cleared to a remarkable degree in approximately 7 to 10 days, at which time the membrane completely disappeared in both eyes.

The patient volunteered the information that as soon as the eyes would become well, the mouth would break out into various sores. She was right. This condition in and about the mouth lasted four or five days, and then there was a recurrence of the ocular symptoms, and each time the membrane was more extensive than during the previous flare-up. Dr. Dublin said that he did not know how to treat the condition, since there seemed to be no adequate therapy. He had never seen a case with such an extensive membrane formation. There are other conditions simulating pemphigus; such as, erythema multiforme, dermatitis herpetiformis, and bullous syphilid. There are still other conditions which will produce membranes, both of the pseudo type and of the deep type of membranous conjunctivitis.

As we know, membranous conjunctivitis involves the deep portion of the epithelium or submucous portion and is invariably considered to be due to diphtheria. This patient was not acutely ill, nor was there any rise of temperature. As no diphtheria bacilli were found, the possibility of diphtheria was eliminated. A culture and smear were taken, but the bacteriologist was unable to identify the organism, stating that it was a very rare gram-positive bacillus.

The patient had two more flare-ups associated with new lesions in the mouth. No special treatment was ordered, since the condition would clear up under simple, bland medication. The patient, however,

received sulfanilamide, internally, in doses of 60 gr., daily, for approximately 10 days. The disappearance of the membranes, Dr. Dublin believed, was not due to the sulfanilamide, because they cleared up without it after previous attacks. When the patient was last seen all the lesions and membranes had entirely disappeared. It is significant that the cornea was at no time involved. There were no vesicles, nor any ulcer formation. The conjunctivas, both tarsal and bulbar, in spite of the dense membrane which was present, at no time showed any bleeding or ulcerated areas, or areas of adhesion. The vision at all times was 20/20 in each eye.

Pemphigus is a rare disease. It may assume an acute or chronic form. The acute form, occurring chiefly in butchers, is a virulent type, with marked constitutional symptoms, and frequently causes death. Chronic pemphigus is frequently called essential shrinkage of the conjunctiva. The cause is unknown, but it is associated with bullae in the skin and mucous membranes in various parts of the body. In the eye, vesicles are rarely seen in the conjunctiva. In their place, however, are small reddened areas, probably the end result of broken bullae. This condition is frequently incorrectly diagnosed or, at least, a proper diagnosis is not made until the late stages, when shrinkage of the conjunctiva takes place. The shrinkage of the conjunctiva is due to connective-tissue formation in the submucous portions of the conjunctiva. When this occurs, there is thickening of the conjunctiva with symblepharon formation and, eventually, ankyloblepharon.

Slitlamp examination in the late stages usually reveals perivascular thickening along the vascular network, together with a parchmentlike appearance of the conjunctiva. Vesicles in the cornea are seldom observed, but corneal changes do

occur secondary to the conjunctival pathologic alteration. The diagnosis is made generally by a dermatologist on the finding of bullae and vesicles in the skin and in the mucous membranes of the body, especially the mouth, larynx, nose, and rectum. A pseudomembranous formation with a chronic type of conjunctivitis is sometimes seen. The membrane affects both the tarsal and bulbar conjunctivas, in contrast to the true pseudomembrane which affects only the tarsal conjunctiva.

In the case presented by Drs. Klauder and Cowan, vesicles were noted in the skin and in the mucous membrane of the mouth, with a history of numerous exacerbations. The eye findings consisted of a membranous conjunctivitis, with numerous flare-ups, and with complete disappearance of this membrane in 7 to 10 days. Although the conjunctiva has shown no permanent defect, in all probability there will be alterations of the conjunctiva. Time alone will confirm or disprove the diagnosis of pemphigus in the case.

Dr. William Lamotte said that, Dr. Klauder had stated that there is no laboratory test for pemphigus. There is reported in the literature, however, a so-called Macht test with which he was not familiar. He asked Dr. Klauder to describe this test and tell whether or not it had any value.

Dr. W. E. Fry suggested that another differential diagnosis may at times, have to be considered; namely, the difference between a vernal conjunctivitis and pemphigus. He mentioned this because of a case that had come under his observation about a year and one half earlier. The patient was seen by Dr. Klauder—a young woman who gave the history of having multiple lesions of the gums, which necessitated the removal of all of her teeth. Exactly what the lesions were was not known.

When this patient was first seen, the

ocular condition was that of papilloma formation over the palpebral conjunctiva. The symptom of which she complained was intense itching. This led to the belief that the condition was vernal conjunctivitis. Smears showed an enormous number of eosinophiles. There were numerous nodules. A biopsy specimen of one of them showed the tissue to be similar to that from cases clinically diagnosed as vernal conjunctivitis.

Dr. Klauder saw the patient, found evidence in the mucosa of previous lesions, and believed that the patient had pemphigus. The patient has since died. Except that it was not an accident, the exact cause of her death was not known. Presumably, however, Dr. Klauder's diagnosis of pemphigus is correct.

Dr. Warren S. Reese said that he would like to ask Dr. Klauder whether, in his experience, cases of ocular pemphigus usually show skin lesions?

Dr. Joseph V. Klauder answered Dr. Lamotte by stating that he did not think the Pels-Macht test an infallible means of diagnosing pemphigus. False positive reactions are obtained, and the consensus of opinion is that it is unreliable.

He could not, offhand, give the percentage of patients with ocular pemphigus in which the disease exists without involvement of other mucous surfaces and without skin lesions. It may occur without other lesions. It may occur with mucous-membrane lesions, and it may occur with mucous-membrane lesions and skin lesions. In answer to Dr. Reese's question, however, he believes that only in the minority of patients is the disease confined to the conjunctiva. He estimated this minority to be about 25 percent. The literature is quoted to this effect in his paper with Dr. Cowan, "Ocular pemphigus and its relation to pemphigus of the skin and mucous membranes." (Amer.

Jour. Ophth., 1942, v. 25, June, pp. 643-66.)

HERPES ZOSTER OPHTHALMICUS APPEARING AFTER TRAUMA

DR. JOSEPH V. KLAUDER (by invitation) reported seven cases of herpes zoster, appearing after injury to the skin or to the cornea, inflicted in various ways and of variable degree. The disease appeared in the region of injury after an interval varying from about one to nine days. In some of the patients, symptoms of sensory disturbance or pain intervened between injury and outbreak of herpes zoster.

Of the seven patients, four had herpes zoster ophthalmicus. The injuries preceding appearance of herpes zoster ophthalmicus were: (1) foreign body in the cornea; (2) contact of the eye and forehead with sulphur dioxide; (3) bumping one side of head on a hard object without producing demonstrable injury to the skin, in two patients.

Review of the literature disclosed many reports of herpes zoster appearing in from 1 to 30 days after injury, at times trivial, to the skin or cornea. Herpes zoster had also been reported as appearing after lumbar puncture, after intramuscular injection of a medicament, after osteopathic manipulation of the spine, and after deep X-ray therapy in the region of a ganglion.

The etiologic mechanism of herpes zoster appearing after trauma was discussed. The incubation period of spontaneously occurring herpes zoster and of the disease when experimentally produced was discussed.

From considerations discussed, it was reasonable to assume that trauma may precipitate herpes zoster. The minimum degree of trauma and the interval between trauma and the appearance of herpes

zoster, in order to ascribe to trauma a causal role, cannot precisely be defined. From experimental evidence and clinical observation of spontaneously occurring zoster, the incubation period of the disease ranges from a few days to about two weeks. From the cases now reported of zoster appearing after trauma, and from a review of the literature, the intervals which predominate are one day to about three weeks.

Dr. Walter Lillie said that Dr. Klauder's presentation interested him, inasmuch as the cases he had reported concerning the use of smallpox vaccine in the treatment of herpes zoster ophthalmicus had no history of trauma. Since Dr. Klauder's cases show such a great variation in the time of onset after trauma (less than a day to six weeks), a real doubt can be raised as to the importance of the trauma. It is well known that it is not difficult to elicit trauma in almost any history of any type of condition. He recalled one case seen at the Mayo Clinic in which a patient, with blindness in one eye and a very small field of vision remaining in the other due to a pituitary tumor, received \$2,500 when the court agreed that the visual loss resulted from a pair of pliers striking his forehead. It is agreed that herpes zoster is a virus disease, that belongs to the chickenpox family, having a definite incubation period of at least a week or more. This explains why many times herpes zoster and chickenpox can be found in the same family.

Dr. George F. J. Kelly said that, at the present time, he had under his care a patient with herpes zoster ophthalmicus. According to her statement, five days previous to the appearance of the lesion some hot lard had splashed on the involved area. He felt this to be coincidental and not causative.

Dr. Joseph V. Klauder replied that ex-

periments made to ascertain if zoster is caused by a virus have given conflicting results. The opinion is stated by some that it has not been conclusively shown that zoster is caused by a virus and that the disease may represent a syndrome resulting from any process causing inflammation of the spinal ganglion. Others accept experimental evidence as valid proof of virus causation and regard the elementary bodies demonstrable in herpes zoster vesicles, particularly within the first 48 hours, as representing the specific virus of the disease. Proof of virus cause of zoster is not so readily demonstrated as is such proof of herpes simplex.

SURGICAL METHODS OF TREATING PARALYSIS OF THE SUPERIOR OBLIQUE MUSCLE

DR. WILLIAM E. KREWSON, III, said that isolated, unilateral paralysis of the superior oblique is frequently encountered; bilateral involvement, occasionally. The pathologic physiology of ocular movements of such cases was reviewed.

The literature records relatively few cases treated surgically, and for these a great variety of procedures has been offered. At some time or other, most muscles attached to each eye have been used in one way or another. These include: (1) weakening of the homolateral superior rectus; (2) advancement of the homolateral inferior rectus; (3) advancement or transplantation of the homolateral external rectus; (4) weakening of the contralateral inferior rectus; (5) tenotomy or recession of the homolateral inferior oblique; (6) shortening of the contralateral superior rectus; (7) advancement of the paralytic superior oblique; (8) various combinations of two or more of these operations.

No standard sequence of corrective measures can be advocated for all cases. The plan of attack must be based on

measurements found in each individual case. If a choice is permitted, weakening of a depressor muscle is undesirable; strengthening of a depressor or weakening of an elevator is preferable. In bilateral cases, equalization and preservation of the remaining depressors is advisable.

Discussion. Dr. Francis Adler said that he would like to amplify one of the factors which Dr. Krewson mentioned, a factor which occasionally leads to an erroneous diagnosis of these cases. He believed that this condition was first pointed out by Chavasse, under the term "inhibitional palsy of the contralateral antagonist." It is seen in those cases in which fixation is customarily carried out by an eye with a paralyzed superior oblique. In these cases, there is not only a characteristic limitation of movement downward and to the side opposite the paralyzed superior oblique, but there is also limitation of movement of the non-paralyzed eye on looking up to the ipsilateral side. For example: In a case of paralysis of the left superior oblique, the left eye fails to move down when the eyes are turned down and to the right. In such a case, the right eye fails to move up when the eyes are turned up and to the right. This may easily be mistaken for a paralysis of the right superior rectus muscle. Dr. Adler believed that the explanation for this so-called inhibitional palsy is somewhat similar to the explanation of the vertical separation on looking down and to the right when the left superior oblique is paralyzed. The vertical separation on looking down to the right is due to two factors: (1) the weakness in the left superior oblique muscle; (2) the overaction of the right superior rectus. This overaction is due to the well-known law of Hering, that all voluntary movements are brought about by an equal innervation to the muscles of the

two sides concerned in the movement. When we look down and to the right an equal innervation is sent to all of the muscles of the two sides which carry the eye in this direction. When one of these muscles is weak, the total amount of innervation is increased so as to bring about the full movement of this weak muscle, but the same amount of innervation is sent to the yoke muscle of the opposite side and so this muscle overacts.

On looking up and to the right, in a case of left superior oblique paralysis, when the left eye is fixating, the movement in this direction is made easier if the left superior oblique is paralyzed, because the left inferior oblique now has no resistance from its opponent. Less energy will be required therefore, to turn this eye out, up, and to the right; accordingly, less innervation is sent to the yoke muscle of the left inferior oblique—namely, the right superior rectus—and this eye fails to move up as far as the left.

Dr. Glen G. Gibson said that he had had experience with mistaken cases of superior-oblique palsy. One of the common types of cases in which the diagnosis may be incorrect are those simulating convergent strabismus. These were cases of palsy which started out primarily as a superior-oblique condition but, as time passed, they became concomitant, and it was almost impossible to differentiate them from cases of ordinary accommodative-convergent strabismus. In some of these, he at first failed to recognize their vertical origin and had operated as if they were cases of convergent squint, only to have them return with unsatisfactory results. Further study would then reveal that they were originally trochlear cases. A second operation produced gratifying results, because the surgical procedure recognized the primary pathologic involvement. Dr. Krewson believed that careful atten-

tion to the sensory correspondence was helpful in selecting the proper type and amount of surgical correction.

He illustrated the simplest operation by presenting a traumatic case of trochlear palsy of a year's duration in which there was 21 prism diopters of hyperphoria. This patient was subjected to a recession of the inferior rectus of the opposite eye. Following the operation, which consisted of a 2-mm. recession of the contralateral inferior rectus, there was no hyperphoria. In other words, the 21 prism diopters of hyperphoria had been reduced to zero by a minimal recession.

The important point in this case was not that it was an instance of very precise measurement of the amount of necessary surgical correction, but rather that a good surgical result was achieved because this patient originally had, and, until his accident, had always had, normal binocular vision. What was done was to put the eye somewhere near the normal place, and since the patient had normal binocular vision, the sensory mechanism helped to bring the eyes to the precise place where they were wanted.

If the case is long standing or congenital, a 2-mm. recession is not adequate for bringing about the desired result, particularly in cases that present a marked vertical tropia. In such cases it is necessary to do a recession of as much as 4 or 5 mm., about the maximum recession possible in the inferior rectus of the other eye. In some cases, especially those of long standing in adults, it is necessary to combine both the recession of the inferior rectus of one eye with a tenotomy of the inferior oblique of the other, or paralytic eye.

One other important point is the recognition of birth traumas and hereditary factors as a cause of trochlear paralysis. Recently two grandmothers, who have

had that condition all their lives, were seen. They were grandmothers of two patients on whom operations for trochlear paralysis had been performed. This shows a definite hereditary factor for which the ophthalmologist should look.

Birth trauma is a common cause. It is fruitful to investigate these cases, particularly for the history of forceps delivery as a possible cause of original trochlear palsy. It is also important to recognize the degree of binocular vision that these patients have. If the condition has been present from birth, the individual never did have binocular vision except with an abnormal position of the head. A much more extensive surgical procedure is needed in these cases than in those of traumatic origin.

GEORGE F. J. KELLY,
Clerk

COLORADO OPHTHALMOLOGICAL SOCIETY

October 20, 1945

DR. WALTER OMHART, *president*

CHOROIDITIS TREATED BY PENICILLIN

DR. GEORGE H. STINE presented H. H. P., a white woman aged 35 years, who had first been seen about five weeks previously. She gave a history of previous attacks of choroiditis. At this time she had a large, atrophic, healed area with a fresh patch of exudate nearby, accompanied by paraphlebitis. The lesions resembled tuberculosis, but the tuberculin tests were negative. There was considerable peridental infection. The condition had improved following dental extractions, and foreign protein, atropine, and penicillin therapy.

RETINAL DETACHMENT, MYOPIA, MULTIPLE HOLES

DR. GEORGE H. STINE presented Mr.

W. C. K., aged 50 years, whom he had first seen on June 12, 1945. The patient complained of having had blurred vision for several weeks. This became much worse after an automobile drive over a rough road. Interesting features of the case were the high myopia and the presence of three holes. One near the macula was treated by galvanism. After treatment with perforating and nonperforating diathermy in the peripheral-tear areas, the retina was almost entirely reattached. A second operation, treating the region of the peripheral tears, was performed on September 6, 1945. At this time the retina was completely reattached with corrected vision of 20/200 in the right eye. Dr. Stine said that after retinal-detachment operations, there is an exaggeration of normal phenomenon; that the periphery is seen with more plus than the macula. This was illustrated in this case in that the macula was best seen with a minus 11 sphere whereas the peripheral-tear areas were seen with a plus two sphere.

RETINAL DETACHMENT, MULTIPLE OPERATIONS, POSTERIOR SCLEROTOMY

DR. GEORGE H. STINE presented Mrs. C. W. G., aged 67 years, who had been seen in 1931 and 1934 because of vitreous opacities. On June 18, 1934, a retinal detachment was found in the upper nasal quadrant of the left eye by Dr. Neeper. Pinhole glasses were prescribed, and the retina reattached by July 8, 1934. The detachment recurred on July 24th. It was larger than the previous one, but improved after bed rest and dental extractions. Surgery was performed in the upper nasal quadrant by Dr. Clifford Walker on August 13, 1934. The patient was operated on again by Dr. Stine on August 27, 1934. At this time a posterior sclerotomy was done in the lower nasal quadrant.

A tear then developed in this area which Dr. Stine attributed to the posterior sclerotomy. A third operation was performed by Drs. Walker and Stine in the upper and lower nasal quadrants on September 17, 1934. The retina reattached 10 days later. At the time of presentation of the patient (11 years later), there were some drusenlike opacities in the macula, a few vitreous opacities, and a small posterior capsular cataract. Slit-lamp and plano-contact-lens examination showed marked forward contraction and shrinkage in each eye. The retina of the left eye was still in place, and the corrected vision was 20/30.

OSTEOMA OF THE ORBIT

DR. K. H. CHAPMAN presented G. R., a boy aged four years, who had had a swelling at the outer canthus just inside the lids since birth. When he was one year old, the swelling had been "opened" by an ophthalmologist, but the size had remained the same. On examination, Dr. Chapman found a narrow band of scar tissue in the conjunctiva extending from the outer posterior canthus for about 5 mm. Posteriorly and temporally to this was some fullness, but no definite mass could be palpated. The preoperative diagnosis was "accessory lacrimal gland which had become cystic."

While the child was under a general anesthetic for a tonsillectomy, a mass was dissected from the orbit just posterior to the lateral orbital margin, to which it was not connected. It was a firm, lobulated, freely movable, well-encapsulated mass about 2 by 1½ by 1 cm. in size and similar in appearance to a lacrimal gland. The pathologic diagnosis, however, was "osteoma." Dr. Chapman said that osteomas, invading the orbit from the sinuses, are relatively common, but that she had found no recent reports of one in the

temporal orbit unconnected with the orbital wall.

MICROPHTHALMOS, HARELIP, AND CLEFT PALATE

DR. GEORGE H. STINE showed a kodachrome picture of an infant born with a major cranial deformity and other associated malformations including bilateral microphthalmia.

Discussion. Dr. William H. Crisp mentioned a case of microphthalmia associated with marked corectopia.

Another member said that he had recently seen a child with microphthalmia associated with a white congenital abnormality in the vitreous. In discussing the differential diagnosis, the question was asked whether any member present recalled ever having seen a case of retinoblastoma in one of these small eyes. No one remembered having seen such a case.

ACUTE GLAUCOMA, PARACENTESIS

DR. WILLIAM BANE reported the case of an elderly lady who had had an attack of acute glaucoma which had not responded to miotics. He had then performed a paracentesis, and the tension had immediately come down to normal and had remained so with a minimum of medication.

Discussion. Dr. William H. Crisp said that in some of these paracenteses and in Curran's operation we, in essence, had a small iridencleisis.

CATARACT, RECURRENT IRITIS, AND DEAFNESS SECONDARY TO INJURY BY LIGHTNING

DR. V. H. BROBECK and CAPT. C. A. FLEISCHLI presented G. W., a 22-year-old pilot of a B29 bomber, who had been struck by lightning four months previous-

ly, just as he had stepped out of his plane. He was unconscious for 36 hours but had made a complete recovery except for deafness in his right ear, diminished vision in both eyes, and recurring attacks of iritis. The poor vision was first noticed about a month after the accident, and examination revealed the cause to be capsular cataracts. Two months following the injury, the vision had been reduced to 20/50 in the right eye and 20/40 in the left. There had been no further loss of vision nor progress in the opacities since then. No foci of infection were found to account for the recurrent iritis. Dr. Brobeck said it was interesting to speculate on the manner in which the iritis was caused by the lightning. The iritis had responded to cycloplegics and foreign protein. An interesting feature of the case was the fact that the lightning had burned the amalgam fillings out of his teeth. The patient has an amnesia for events just prior to the injury.

Discussion. Dr. George H. Stine mentioned that in a family of three which was struck by lightning, two of the members developed cataracts and one was not affected.

Dr. R. W. Danielson said that the interval before developing cataracts was similar to that in dinitrophenol cataracts. In both cases the cataracts are probably secondary to the effect on the germinal epithelium of the lens.

Drs. W. A. Ohmart, J. W. Lamme, and E. R. Neepier also reported having seen cases of cataract secondary to injury by lightning.

TUMOR ON THE DISC

DR. FRITZ NELSON presented J. E. W., a white man, aged 61 years, who said that about five years before, the vision of his left eye had deteriorated somewhat due to a fundus lesion of uncertain ori-

gin. The vision of the right eye had always been good. About $2\frac{1}{2}$ years later, a little node began growing slowly below the left lower jaw bone. He was sent to the cancer clinic and received about 25 X-ray treatments to the left side of the naso-pharynx, whence the primary tumor had supposedly originated. The tumor below the jaw was not treated.

The patient was first seen by Dr. Nelson on January 26, 1945. At that time the tumor below the jaw was about the size of a hen's egg, very firm, and not attached to the skin and deeper layers. There was no dislocation nor exophthalmos (Hertel, 18 mm.) of either eye. The corrected vision of the right eye was $5/3$ and of the left $5/6$. Ophthalmoscopically, the right eye had a white prominence (about $2\frac{1}{2}D.$) at the lower edge of the disc, which was partly covered by it. The formation resembled a bundle of medullated nerve fibers, but seemed to be globular in shape and more prominent than one would expect.

Dr. Nelson was suspicious of a metastatic tumor on the right optic disc. The probable general diagnosis was: "a slow-growing malignant tumor (sarcoma or mixed tumor) of the left, submaxillary salivary gland. The condition had not shown much change during the past nine months. Dr. Nelson planned a biopsy of the tumor below the left mandible.

Discussion. Drs. William M. Bane and George H. Stine and others believed the tumor was composed of medullated nerve fibers in spite of the elevation.

MALIGNANT MELANOMA OF IRIS AND CILIARY BODY

DR. FRITZ NELSON presented P. B., a white man aged 51 years. The patient was first examined in the fall of 1941, and neither eye showed any abnormality. In October, 1944, during a routine refraction, a small dark chocolate-brown fusi-

form tumor was found between the 7:30 and 8:30 positions, involving the root of the iris of the right eye. This tumor was about 3 mm. long and not quite 1 mm. wide. All functions of that eye, including the field of vision and visual acuity, were normal. Malignant melanoma of the ciliary body was suspected at that time, but no protrusion of a tumor from the ciliary body backward could be seen.

On April 4, 1945, the patient was re-examined. The tumor of the iris was of about the same size, but now protrusion from that region into the vitreous body could be seen ophthalmoscopically. The size of the tumor in the ciliary body was that of a very small pea. Because of the early stage, it was planned to destroy the tumor with a diathermic needle. The patient, following the advice of another ophthalmologist who told him that the eye was perfectly normal, refused treatment.

He was seen again on October 20, 1945, and a definite increase of the tumor could be seen ophthalmoscopically. The tumor was surrounded by a translucent or semi-opaque zone, and the equator of the lens showed a small opacity probably caused by some influence from the tumor. Dr. Nelson thought that enucleation of that eye was now probably the only choice.

Discussion. Dr. George H. Stine advised a diagnostic iridectomy, examination of a frozen section and removal of the eye if the tissue showed malignancy.

Dr. R. W. Danielson said that the presence of the opacity in the lens was confusing. He recalled a case in his practice in which, with an undilated pupil an opacity of the periphery of the lens had ophthalmoscopically given the appearance of a tumor in the ciliary body.

RALPH DANIELSON,
Acting Secretary.

DR. K. C. BRANDENBURG, *presiding*

CLINICAL ASPECTS AND TREATMENT OF EXOPHTHALMOS FROM THE EXPERI- MENTAL VIEWPOINT

DR. HARRY FRIEDGOOD reviewed the anatomic and physiologic aspects of experimental exophthalmos in lower mammals and correlated them with the clinical picture of exophthalmos in man. He stated that it was possible to produce exophthalmos in experimental animals by means of anterior-pituitary injections much more easily after removal of the thyroid gland than before. Dr. Friedgood said that of the various possible explanations for the mechanism of exophthalmos due to thyroid disease, it seemed that edema of the orbital tissues was the most likely.

It was concluded by Dr. Friedgood that the exophthalmos of this syndrome goes through two phases, the reversible and irreversible. He said the former was ordinarily encountered in exophthalmic goiter. The latter, he said, occasionally occurs as a postthyroidectomy complication.

The evidence, he pointed out, suggested that an exophthalmos-producing (ophthalmotropic) factor in the pituitary gland, distinct from the thyrotropic hormone, induces both types of exophthalmos. The use of the word ophthalmotropic, he said, does not imply that a specific chemical substance having the physiologic action is believed to exist as such in the pituitary gland. Dr. Friedgood said that

because this factor is probably responsible for edema of the orbital tissues, it might be tied in with the important role which the pituitary and thyroid glands play in regulating water metabolism.

Although the irreversible or malignant type of exophthalmos cannot always be differentiated in advance from the benign or reversible type, certain clinical criteria aid in the diagnosis. Since edema of the orbit is probably an early pathologic change, one should regard with suspicion any preoperative chemosis, lacrimation, puffiness, or venous congestion of the lids or orbit. The development of hyperthyroidism during iodine therapy or the presence of thyrotropic hormones in the urine should put one on guard, according to Dr. Friedgood, as should a low basal-metabolism rate and increase in blood cholesterol.

He also stated that males with slight hyperthyroidism and considerable exophthalmos are peculiarly predisposed to the development of malignant exophthalmos following thyroidectomy. In his opinion operation should be avoided in suspicious cases or, if operation is necessary, the pre- and postoperative administration of desiccated thyroid may prevent the development of hypothyroidism, which is known to favor the development of malignant exophthalmos.

NEUROTICISM AMONG ANISEIKONIA PATIENTS

DR. K. C. BRANDENBURG, in collaboration with his associate, Dr. Hazel Wentworth, made a preliminary report on a study of the neurotic factor among aniseikonia patients (utilizing the Harrower-Erickson modification of the Rorschach test). They had divided a series of 50 patients into three groups and scored them according to their percentage of poor

answers on the Harrower-Erickson multiple-choice test as follows:

	<i>Number Cases</i>	<i>Median Score*</i>	<i>Average Score* percent percent</i>
Group I			
No symptoms—no aniseikonic test	7	6.5	12
Group II			
Symptoms—1% or more aniseikonia			
A. Marked or complete relief	23	11	15
B. Partial relief	9	23	21
C. No, or only slight	10	40	39
Group III			
Symptoms—No aniseikonia or less than 1%	11	20	27

* Scoring of H-E Rorschach: 0 percent—no poor answers; 100 percent—all poor answers; under 40 percent—normal; 40 to 50 percent—borderline; over 50 percent—disturbed personality.

Dr. Brandenburg called attention to the limited number of cases tested in each group, rendering the reliability of the results somewhat questionable. He also pointed out that the averages for all groups fell within what was considered the normal range of bad answers.

There was, however, a definitely greater average of bad answers among aniseikonia patients who received no, or only slight, relief from their correction (39 percent) than among those who received complete relief (15 percent), or only partial relief (21 percent). Whether the

percentage of bad answers within the normal range could be considered a criterion of a degree of neuroticism had not been established experimentally as far as the essayists were aware. Dr. Brandenburg reported that the figures seemed, however, to corroborate the clinical impression that when aniseikonia exists in an individual who does not manifest marked neurotic tendencies, isekonic lenses are more likely to give lasting relief than in cases wherein the neurotic factor is of greater importance. He stated that the study would continue.

PSYCHOLOGIC PROBLEMS OF IMPENDING BLINDNESS

MR. J. MILTON JOHNSON of the Braille Institute stressed the psychologic importance of acquainting persons with impending blindness with the many activities, useful and diverting, which are available to the blind. He thought it to be desirable that they learn these things from someone who was, or had been, blind and could therefore understand the hopes and fears of one whose vision was failing or had failed. He described the various activities of the Braille Institute of America and asked the coöperation of the eye specialists in making these contacts possible.

KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*,
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois*; Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin*.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

FEDERAL INVESTIGATION OF REBATING

In a Saint Louis newspaper of July 24th appeared this headline: "Anti-Trust Suits Charge Rebating to Eye Doctors" and, in a subheading, "Civil Actions name Seven Concerns, about 5,000 Individuals, and ask for Injunctions."

I quote the first paragraph of the article: "The Department of Justice today filed two civil suits in Federal Court charging optical wholesalers and approximately 5,000 leading eye doctors through-

out the country with violating anti-trust statutes." Thirty eye doctors were named in "a representative capacity" representing 3,000 doctors who are accused of receiving rebates regularly from one company. Another company is accused of rebating through its subsidiaries to another 3,000 eye doctors. Allowing for some overlapping, probably 5,000 eye doctors are involved directly or indirectly in the suit. There are about 7,500 ophthalmologists in the nation. Approximately two thirds are, therefore, accused.

Since writing these introductory paragraphs, there have appeared copies of the indictments in the Journal of the American Medical Association and an editorial in the same issue which merely stated the resolutions passed previously by the Ophthalmic Section and the action of the House of Delegates on these resolutions.

In other newspapers, in addition to the names of the representatives in the two indictments, there apparently appeared the names with the amounts allegedly rebated to some of the ophthalmologists.

The writer has always strongly contended that it is ethically wrong to take a hidden fee from a patient and that an ophthalmologist should not profit in any direct financial way from the sale of lenses or their appurtenances. This is the rule of ethics of the American Medical Association, but it has admittedly been disregarded by many members of its official Eye Section.

In discussions of the matter, one often encounters the comment "Granted that the practice is current, surely you don't want the public to lose confidence in the eye doctor by letting people know about it." The answer is that no one should have the public confidence if he does not deserve it. One usually then hears the statement that those in the eye specialty are not alone guilty, that rebates are taken on orthopedic appliances, ear phones, drugs, and other items, so why should ophthalmologists be singled out for punishment. Obviously, everyone who engages in such practices should be called to account, but unethical conduct in one person is not a good excuse for it in another, and it is the ophthalmologists' misfortune that they have been selected for action.

What a perfect opportunity this well-known practice has given to those whom ophthalmologists have attacked on ethical and moral grounds to say

"Look who are calling the kettle black."

Unfortunately, we could not or, at any rate, would not handle this matter within our own profession so now the Federal Government has taken the task over.

Whether doctors who accept rebates are legally liable or not is not for the writer to say. If the doctor has failed to show in his income tax report any money received, that is another story and no lawyer is needed to answer that question, and the eye physician would better engage a good one to defend him. The rebater has surely had the transactions on his books and, undoubtedly, the Government has already secured these books containing the lists of names and amounts rebated.

It would probably be desirable for the profession to know everything about these matters. The writer guesses that, unfortunately, there are some in very high places whose names are on these lists. Whether it would have a salutary effect or not for everyone to know the names of those who engage in these doubtful practices is a moot question. Frankly, the writer would not enjoy seeing them exposed before their friends and patients. Actually, some of this may never happen but the indictments bring up once more this disagreeable problem that has thus far baffled all who have tried to eliminate it. Medical disciplinary action in this matter must of necessity fall upon the American Medical Association because the Ophthalmic Section has no authority to handle it. By the nature of the Constitution of the American Medical Association, ultimate discretion in regard to ethics rests with the county medical societies, and the Ethics Committee of the House of Delegates, if it takes any action at all, will probably refer the matter to these hundreds of county organizations, possibly after a few generalities on the subject. It is not necessary to comment on the complete lack of action that

would be taken by most of the local medical societies.

But is not there anything that can be done to eliminate these unwholesome practices that cast opprobrium on all physicians and furnish good grounds for the Government's lack of faith in the ability of the medical profession to act in the best interest of the public? The Government apparently is now fully aware of the existence of rebating and believes it is illegal and harmful to its citizens. We must agree that it contributes to increase the cost of glasses and that in itself is detrimental to the general welfare. Wholesalers and retailers alike must surely want the practice stopped. It does them no good and is financially harmful.

The writer suggests that the Executive Committee of the Section on Ophthalmology of the American Medical Association appoint a committee to confer with Government agents, wholesalers of optical goods, and representative retailers for a frank discussion and an effort to adopt a course to bring about a termination of this abuse. The Government may frighten some out of rebating and receiving rebates, but the coöperation of all of those interested in the matter might prove even more effective than the governmental warning and fining of a few individuals selected to be the scapegoats for other possible offenders.

National and local ophthalmic societies and The American Board of Ophthalmology have no police powers and should not have, their functions are other than this, but a stronger attitude by them on "kick-backs" and rebates would be helpful in stamping out this pernicious practice and would more definitely indicate to the young men entering our specialty our wholehearted disapproval of it.

Lawrence T. Post.

A STANDARDIZED CURRICULUM

The need for more graduate courses in ophthalmology is as acute as it is obvious. The number of applicants for such training is tremendous. The reason for the large number is not difficult to find. Many physicians, while serving in the Armed Forces, were brought into contact with ophthalmology, usually under the guidance of a well-trained, older man. The result is that they would like to choose it for their own specialty.

The interest thus stimulated is no idle one, no passing fancy, but rather it is deep and sincere. The ultimate goal of the large majority is certification by the American Board of Ophthalmology. This is gratifying and is as it should be. One has but to interview these men to be convinced of their sincerity and singleness of purpose.

The available graduate courses in ophthalmology are few. These few are probably satisfactory, but no doubt there is room for improvement. Each course has its strong points, depending upon the interests of its faculty; similarly, each course has its weak points and for the same reason. It behooves us to take stock of our courses, to examine critically their curricula. How well are they preparing candidates for the examination of the American Board of Ophthalmology and, what is more important, for the clinical practice of good, sound ophthalmology? It would be wise to look for weak spots, for they are surely there.

It would be wiser still to have a "stranger" or even a board of strangers examine our curricula than to do it ourselves. It is objective, constructive criticism that is desired. The fresher viewpoint of an outsider would be invaluable.

Such a board might be formed under the auspices of the American Board of Ophthalmology or by any one or all of the

three national ophthalmic organizations. Its function would be to analyze the curricula of available courses with the view of taking the best from each and developing a standardized program for such courses. Just as the American Medical Association inspects medical schools in this country, so should such a board inspect graduate courses in ophthalmology. Our courses are probably good, but they could be made better.

One value of such a standardized curriculum, bearing the Board's stamp of approval, would be that it could be made available to many institutions to serve as a guide for the establishment of more courses. It seems probable that many large institutions have a wealth of clinical material at hand and also a faculty. All that they need is a blueprint in the form of a detailed, standardized, approved curriculum and a little encouragement.

At the moment, those conducting the available graduate courses in ophthalmology are on their toes. They should be kept that way. And other such courses should be initiated. The demand of large numbers of applicants makes it imperative.

Richard G. Scobee.

CENTENARY OF ANESTHESIA

On October 16, 1846, Morton dramatically introduced general anesthesia to the operating theater. The eminent and humanitarian surgeon, John C. Warren, with a courage reminiscent of Joseph Warren, his uncle, who fell at Bunker Hill, risked his great reputation in this hazardous experiment. The patient was Gilbert Abbott, a painter and single.

As now the atom holds the spotlight, so, in the early 19th century, gases and vapors dominated scientific attention. Beddoes became mystically inspired by their possible therapeutic value and, in his

Pneumatic Institute, Davy, in 1800, and Faraday, in 1818, discovered the insensibility produced by nitrous oxide and ether, respectively. These observations excited a minimum of attention. Even as later as 1831, Velpeau pontifically dismissed the hope of ever operating without pain. By 1839, however, the *Materia Medica* mentioned that ether could produce stupefaction. Then Long, at the age of 26, Morton at 27, and Wells at 29—obscure young men ignorant of Velpeau's dictum—demonstrated its fallacy. The concept of "anesthesia" now had a footing, and Oliver Wendell Holmes supplied the word.

But not all were convinced. Wrote Thomas E. Bond of Baltimore in the *Boston Medical and Surgical Journal* of December 15, 1846: "What your correspondents are pleased to call 'producing insensibility' is, in fact, making people 'dead drunk.' . . . Now, doctor, if we are to induce insensibility by this class of means, I very much prefer whiskey-punch to ether, because it is more certain and more permanent in its effects. It is less dangerous, and, lastly, it will be easier to persuade patients to take it."

Before the advent of local anesthesia in 1884, eye surgeons faced the choice of operating under general anesthesia or none and not infrequently decided that the advantages were with the latter alternative. William Mackenzie, in 1854, advocated general anesthesia for children, and for discussion on timid adults. But he continued: "In extraction I have not ventured to use it, being afraid lest the vomiting which is apt to follow might cause rupture of the internal structures of the eye. I have read, however, from others who have used it in extraction, a very favorable account of the complete stillness of the eye which it affords." Henry S. Schell of Wills Eye Hospital, in 1881, expressed the same viewpoint: "If the

patient is of steady nerve, and can be relied on to obey orders promptly, it will be more satisfactory to both parties to dispense with ether. . . . The pain of the incision is not very great, and slight pauses, with closed lids, may be allowed between the steps of the operation." But B. J. Jeffries of the Massachusetts Charitable Eye and Ear Infirmary, in 1871, declared otherwise: "In these days of ether and chloroform, one or the other is always administered, so that the patient suffers no pain, and after the operation is often unable to say which eye was operated on."

Intravenous anesthesia was widely used during the late war in the expeditious surgery of eye casualties only just evacuated from battle, and it proved a priceless boon to the tense, exhausted warriors. Because of its effectiveness and relative simplicity, this latest development of general anesthesia certainly merits wider acceptance for the eye surgery of everyday civilian practice.

James E. Lebensohn.

WETTING AGENTS AND DETERGENTS

References to the use of wetting agents and detergents in ophthalmic drugs became fairly common in 1941 and 1942. There is experimental evidence that important and desirable effects are sometimes produced by addition of specific surface-active agents to certain therapeutic preparations. These effects are: (1) increased solubility permitting higher concentration of therapeutic drugs to come into contact with the eye; (2) increased penetration into the cornea and other ocular tissues; (3) longer persistence of the therapeutic substance in the conjunctival sac in spite of dilution of the drug with tears.

The second of these effects is the one for which the most experimental data have

been presented, but the *modus operandi* is not explained to the satisfaction of the average clinical ophthalmologist. The benefit of using wetting agents or detergents is based on theoretical assumptions as to their action which, to the practical man, is discounted by certain evidence that the desired effects may be produced mainly by damage to the corneal epithelium.

The purpose of this editorial is to discuss the theoretical considerations involved in the use of wetting agents; to attempt to clarify "lowering of surface tension," which is the explanation most frequently encountered; and to review, briefly, evidence of damage to the corneal epithelium.

Because many of the recently introduced synthetic detergents combine properties of wetting agents and detergents in a single molecule, there has been a tendency to neglect any consideration as to whether the specific agent is chosen for its wetting power or detergency. Although knowledge in the realm of wetting agents and detergents is still rather limited, some consideration of the distinctive properties of each might help us to predict the type needed for a specific purpose.

Most detergents are wetting agents, but the very best wetters are not always detergents. A detergent must have wetting properties so that the soil or contamination on the surface will be completely wetted, that is, covered with fluid, whereupon the distinctive property of the detergent comes into play. The detergent lowers interfacial tension between soil and solution and lifts globules of soil off the surface, keeping them in solution or suspension so that they are not redeposited. The lifting of the particles off the surface into the solution is the distinctive action of the detergent. This may be accomplished through surface-action effects, influence on solubility, and by frothing or agitation. Usually, it is accomplished by a

combination of two or more of these factors.

The cleaning of a surface by a detergent can be readily appreciated as important in bringing therapeutic agents into truer contact with the absorbing surface, as, in the case of the cornea, by removal of exudate and detritus from the corneal surface, allowing uniform distribution of the solution over the entire surface. We have all observed how dew occurs as spherical drops of water on the surface of a leaf. Between the drops there is an exposed dry surface. The exposed surface will always have on it dust, insecticide powder, or other finely divided substances of some sort. In a heavy shower, all the dust is washed off, and the remaining water no longer forms drops but wets the whole leaf and forms a thin layer over the whole surface.

A wetting agent, like a detergent, lowers interfacial tension so that there is wetting with spreading of the fluid over the surface, but it does not necessarily clean the surface. It may leave the contaminating particles still adherent to or, in spreading, wash them onto another part of the surface.

How does a wetting agent induce a solution to spread over and penetrate into a surface?

We all know the theory that the molecules in any substance attract each other by electrical forces. We readily see that the attraction forces in the interior of a mass of liquid will be balanced in all directions but that, at the surface, there will be an uneven distribution of forces inward. The cohesive forces holding the substance together are not balanced at the surface, and there is a pull toward the interior exerted on the surface layers. To break this surface, it is necessary to do work, to exert force. Since this surface force is uniform, due to the averaging effect of the very large number of molecules per

unit of surface area, and since it tends to produce a surface with the smallest possible area, there results a spherical shape in any drop of liquid free from the effect of gravitational forces. The work required to overcome this surface force is called the surface tension.

Now, if there are two constituents of a solution and the molecules of one have a higher attractive field of force around them than the molecules of the other, and, if the molecules of higher attraction are present at the surface, a liquid with a comparatively high surface tension results. Contrariwise, if the molecules with the smaller fields of force are at the surface, the surface tension is smaller. Since the molecules are free to move, the liquid will always tend to cover itself with the molecules of the constituent possessing the smallest field of force. Consequently, we choose, as a wetting agent, a substance with low cohesive forces, and we cover the matrix fluid with a film of the wetting agent. Thus, we modify the surface tension of the fluid, lowering it so that it has less tendency to conglomerate and more tendency to spread.

If the attraction of the matrix liquid for molecules of the added substance is greater than their cohesive forces, the added liquid, or solid, will spread and, in so doing, the substance forms a film over the matrix liquid. If the cohesive forces are sufficiently weak, the added substance will spread uniformly over the surface. The action of a surface-active agent in wetting is, therefore, due to the repulsive forces which occur between molecules of the agent collected as a film on the surface of the main body of fluid. This repulsion resists the concentrating effect of the contraction forces existing on the surface layer of the main body of fluid. It is a repulsion that not only counteracts these contraction forces but also acts to push the matrix fluid into corners and over sur-

faces that would not ordinarily be wetted by this fluid. The surface-active effect depends on the molecules remaining as a film on the surface.

Langmuir, in 1917, introduced the ideas, still accepted, concerning the orientation of the molecule in these surface films. These ideas are discussed by Roth (*Amer. Jour. Ophth.*, 1946, v. 29, p. 717). To illustrate, for one group of substances: Molecules of fatty acids and alcohols contain the water-soluble, hydrophilic groups (OH and COOH) and water-insoluble, hydrophobic groups. The hydrophilic groups tend to solubilize the molecule. In the case of shorter chain molecules, as methyl and ethyl alcohols and acetic acid, these groups are sufficiently hydrophilic, unbalanced by hydrophobic groups, to solubilize the entire molecule and, therefore, leave no surface effect since the alcohol or acid is readily diffused beneath the surface of the matrix fluid. With an increase in length of the chain, the solubility decreases, and there is a balance of hydrophilic and hydrophobic groups tending to produce a molecular surface film. As we come to the very-long-chain fatty acids, the solubilizing effect is so retarded that there is no surface film, no spreading, and no effective reduction of surface tension.

If the molecule contains two hydrophilic groups attached to opposite ends, the strong water attraction holds the molecule flat on the surface, resulting in a type of film in which the hydrophobic portions of the adjacent molecules are not in sufficiently close proximity to permit the repulsive forces to become important.

It is apparent that, if a substance is to reduce surface tension effectively, it must have a water-soluble, hydrophilic portion (when water is the matrix fluid, otherwise the solubility must be for whatever matrix liquid is used); and it must also have a water-insoluble, hydrophobic por-

tion in its molecule. A proper balance keeps the agent at the surface; yet, there should be enough attraction to the water to cause spreading of the agent and, with it, spreading of the water.

To illustrate what we mean by balance between end-groups, we might think of the surface-active molecules behaving as would nails stuck into corks in such a way that the nails stand up as masts held at the surface of the water by the corks. Hydrophobic portions of the molecules would be the nail heads; hydrophilic portions, the nail in the cork.

The simplest case of wetting is the result of the spreading action we have tried to visualize as caused by the repulsion between molecules of surface-active agents and the subsequent overcoming of the tendency of the liquid itself to present a minimum surface.

The effect of surface-active agents on surface tension is influenced by the presence of water-soluble salts, such as sodium chloride and sodium sulfate. The salts affect the hydrophilic nature of the water-soluble portion making it less water soluble. For surface-active agents having considerable solubility, decreased water solubility may make an agent more effective in reducing surface tension, and vice versa. The properties of a surface-active agent, such as stability and surface tension, depend largely, therefore, on the nature of the end groups of the surface-active agent and the balance achieved between them. The surface-tension value given for a particular liquid by a surface-active agent is a function of the cohesive forces acting between the molecules of the film. Other things being equal, lowered cohesive forces are desired.

Coupled with low surface-tension factors in wetting are such properties as solubility, substantivity, and the condition of the surfaces. Of two liquids, the one with lower surface tension will spread

more rapidly over a clean surface, other conditions, such as viscosity and volatility, being equal. Or, at equilibrium, the liquid with lower surface tension will cover the greatest area, the qualities involved being equal, regardless of viscosity. As we all know, two drops of clean mercury on a clean plate readily join into a single drop; two less pure drops on a dusty plate become a single drop with difficulty.

Many wetting agents, soap being the most familiar example, are rendered insoluble and ineffective in the presence of heavy metal ions, with a change in hydrogen ion concentration, or with a change in salt concentration. Such influences by the varied constituents of a therapeutic preparation must be considered when a special surface-active agent is to be added.

Another factor which must be considered is that the attraction between the surface-active agent and the surface may not be chemical but physical, induced by electrical charges. This property is said to be substantive. These considerations help us visualize, to some extent, how the addition of a surface-active agent may bring about a closer contact of a therapeutic drug with the surface to be covered. Sometimes, this is accomplished by cleaning the absorbing surface; sometimes, by solubility effects; and sometimes, by increased spreading of a film over a surface.

A consideration of the increased penetration of therapeutically active substances through the cornea leads us to a consideration of the rise of a fluid in a capillary tube. Defining surface tension (γ) as the force in dynes required to extend the surface of a liquid along a line one centimeter in length, we have the formula:

$$\gamma = \frac{h r d g}{2}$$

Where h is the height of rise of liquid in the capillary in cm., r is the radius of the capillary in cm., d is the density of the fluid in g/ml, and g is gravitational acceleration, 980 dynes/cm². We see that, the higher the surface tension, the greater the penetration into capillary pores in the corneal epithelium, unless the value of h is negative. In general, h is positive; that is, when liquid touches the walls of a capillary or pore, the attraction of the molecules of the wall for the molecules of liquid is greater than the attraction of the molecules of liquid for one another. The liquid, therefore, wets the wall of the tube and creeps up the wall to the height calculated as h in the above equation. Obviously, the higher the surface tension, the higher the liquid ascends in the capillary.

If the attraction of the molecules of the wall of a tube for neighboring molecules of liquid is less than the attraction of the liquid molecules for one another (as in the system mercury glass), the liquid will fail to wet the wall and will be depressed rather than elevated, giving a negative value of h . By making a previously non-wetting fluid wet the wall of the capillary, the sign of h may be reversed. For instance, assuming that a membrane has pores of capillary dimensions lined with a fatty material which is not wetted by water, the capillary rise of water in such a pore will be negative. Surface tension, as usually understood in biologic papers, is surface-tension at such an oil-water interface. This surface tension is markedly reduced by such agents as aerosol. If, then, by addition of a wetting agent, as one of the aerosols, sulfosuccinate acid esters, the water can be made to wet the walls of the pore, the rise will become positive. If the height of the pore is less than the height of the capillary rise, the fluid will freely penetrate the membrane.

Assuming that our problem is to stimulate the flow of fluid through a porous membrane, the addition of a wetting agent helps us to accomplish this purpose best if it brings about wetting of the pores with the least amount of coincident lowering of surface tension. A consideration of the paradoxical mechanism of the action of a wetting agent in the penetration of fluid through a capillary pore may help in the choice of a specific wetting agent capable of giving the greatest desired effect.

The following simple diagrams illustrate this idea.

A complete discussion of factors influencing permeability through a semi-permeable membrane would bring into consideration the mechanism of anomalous osmosis, with the complicated concept of a membrane (an aggregate of a number of pores of different sizes), the summation of whose properties is measured by investigation not only of permeability but of diffusion rates, conductivity, dynamic membrane potentials, and so forth. We do not intend to discuss semi-permeable membranes here, only to emphasize the effectivity of wetting as one factor in the theoretical deviation of rate of flow of fluid through a membrane.

When the effectivity of an opthalmic

drug is increased by the addition of a wetting agent, this phenomenon can, theoretically, be attributed to the cleansing action of the wetting agent on the absorbing surface; to the increased solubility of the drug in the epithelium; to the increase of the flow of fluid through capillary pores by bringing about wetting of the pores and, thereby, overcoming the epithelial barrier; or, finally, to the elimination of the epithelial barrier by damage to the corneal epithelium.

Consideration of evidence that the cause of increased corneal permeability in the presence of wetting agents may possibly depend on damage to corneal epithelium is now in order.

Detergents are known to be good protein-denaturing agents. Many are fairly good antiseptics and bacteriostatics. Zephiran has been shown to have a bactericidal effect on *Staphylococcus aureus*.

The addition of minute amounts of a variety of wetting agents and detergents is known to alter certain proteins, poisoning such enzymes as trypsin and lipase, inhibiting the peptic activity of gastric contents, and lowering the biologic activity of lactogenic hormones. These facts make us wonder what harmful results such chemicals may have on the cholinesterase and the lysozym of tears. We ponder the potentialities inherent in inhibiting the activity of these enzymes and others related to the metabolism of the eye. Tears and meibomian secretion, themselves, have constituents which effect the surface tension at the tears-cornea interface, and tears and meibomian secretion, therefore, affect the permeability of the cornea. Tears are a natural wetting agent, and their antiseptic properties, attributable to lysozym, are of considerable importance. We hesitate to neutralize these properties.

Swan (Amer. Jour. Opth., 1944, v. 27, p. 1118) showed that minute con-

centrations of detergents, especially zephiran chloride, as low as 0.025 percent, resulted in a violent reaction in the rabbit eye when injected into the anterior chamber. He reported development of conjunctival edema and desquamation when a single drop of 0.1-percent, zephiran-chloride solution was applied to the human cul-de-sac. Repeated instillations of zephiran chloride in concentrations as low as 0.03 percent produced conjunctival and corneal changes which were reparable when application of the drug was stopped. Leopold (Arch. of Ophth., 1945, v. 34, p. 99) reported conjunctival and corneal damage from repeated applications of detergent solutions, zephiran chloride producing corneal damage in concentrations as low as 0.1 percent. Repeated applications of solutions containing 0.5 percent of each detergent tested definitely retarded regeneration of corneal epithelium, and a 0.1-percent solution slightly retarded regeneration. Alvaro (Arch. of Ophth., 1943, v. 29, p. 615) mentioned increased penetration of sulfonamide compounds into the eye after first using one drop of sodium dioctylsulfosuccinate. This wetting agent is commercially known as decresol OT, and one drop would be very likely to produce corneal damage.

Ginsburg and Robson in the British Journal of Ophthalmology for April, 1945, offer what seem to be the most specious conclusions to date: "The penetration of sodium sulphacetamide into ocular tissues was studied in living rabbits and in isolated ocular tissues. Application of the drug with a wetting agent, Duponal ME dry (derived from Lauryl alcohol), increased penetration of sodium sulphacetamide into and through the cornea. The removal of corneal epithelium caused great increase in penetration of sodium sulphacetamide into and through the cornea; therefore, the epithelium was

acting as a barrier to passage of the drug. The wetting agent did not increase the passage into the denuded cornea (epithelium removed), and so the wetting agent acts by overcoming the epithelial barrier."

They did not say whether the epithelial barrier was overcome by penetration through the barrier because of surface-active effects by the wetting agent, or by damage to the epithelium by the agent. They did suggest that the addition of a wetting agent to sodium sulphacetamide was of value in infections of the cornea and iris. It not only increased the concentration in the anterior ocular tissues but prolonged the period of effective chemotherapeutic concentration.

In conclusion, we might emphasize the advice, given by Swan and by Leopold, that the use of detergents should be considered with a knowledge of their possible toxic properties. In other words, the benefits to be obtained by their use must be weighed against the possibility of damage to ocular tissues in each case for which they are prescribed. Use of detergents in cases where there are abrasions of the corneal surface, might cause regeneration of the corneal epithelium to be unduly retarded. Their use when there are perforations of the eyeball, by injury or operation, might allow sufficient detergent to enter the anterior chamber to produce untoward reaction. These and other possibilities must always be considered.

On the other hand, the seriousness of the condition for which medication is prescribed, particularly the extent of any infectious process, may be so great as to justify any measures that might overcome the infection. The cases in which applications of preparations containing detergents are recommended for use over a prolonged period must be examined at routine intervals to determine whether

any local damage is discernible while it is still superficial.

In brief, we find by theoretical consideration and by actual experimental evidence that certain benefits are attributable to the use of wetting agents and detergents in ophthalmic drugs, but we are left with a realization of the possible toxic effects and a challenge to find better wetting agents with less toxic properties.

S. Rodman Irvine.

OBITUARY

GRADY EDWARD CLAY

1889-1946

Dr. Grady Edward Clay was born November 12, 1889, in the village of Walnut Grove, Walton County, Georgia. He died following a heart attack on July 11, 1946. He was the only child of Augustus C. Clay and Lizzie Chupp Clay. He retired during his last illness to his plantation at Walnut Grove.

Dr. Clay's preparatory education was received in Monroe, Georgia, and Emory College, where he was graduated in 1910. He received his medical degree from the University of Michigan in 1914 and was resident in ophthalmology for the next three years under the able Dr. Walter R. Parker.

He returned to Georgia in 1917 to begin private practice and at that time became an instructor in the eye department of Emory University Medical School. He entered the Army in 1918, serving 18 months overseas with the A.E.F. in France as ophthalmologist in a base hospital. He returned in 1919 and was discharged with the rank of captain. Upon resuming private practice and his association with the department of ophthalmology of Emory University, he rapidly demonstrated his ability and interest in teaching.

Dr. Clay was a member of the Fulton County Medical Society, the Atlanta Eye,

Ear, Nose, and Throat Society, the American Medical Association, Southern Medical Association, Southeastern Surgical Congress, Academy of Ophthalmology and Otolaryngology, and the American

Ophthalmological Society. He served as president and member of the board of trustees of Fulton County Medical Society; chairman of the Ophthalmological Section, Southern Medical Association in 1936; associate editor of the American Journal of Ophthalmology; member of the Council of the American Academy of Ophthalmology; vice-president of the Southeastern Surgical Congress, 1939; and member of the American Board of Ophthalmology. For two terms, from 1936 to 1938, he was president of the Emory University Alumni Association, and served on the university Board of Trustees. He was chairman of the alumni committee that sponsored construction of the present Phi Delta Theta house at Emory University and was elected to Omicron Delta Kappa, national honorary society, for "outstanding service" to the

university. He was a member of the general advisory committee of the National Society for the Prevention of Blindness; and was chairman of the advisory committee on ophthalmology for the Georgia State Department of Public Welfare from 1941 to 1944.

In 1939, he was made chief of the department of ophthalmology and a full professor in 1943. He obtained, through his patients and influential friends, substantial financial aid for the Eye Department and had established a laboratory for ocular pathology and bacteriology.

Grady Clay possessed a forceful personality and was a splendid organizer. In his lectures, he was most instructive to students and staff alike. His great interests were in medical- and neuro-ophthalmology. One of his pet interests was the vascular changes in the retina, and he had striven for years to simplify and gain a more uniform classification of this subject. He spoke repeatedly at the Academy on neuro-ophthalmology in his instructional courses.

In his private practice, he had seen some 70 cases of angoid streaks and was ever searching for the true etiologic factor in these cases. He was an excellent operator, skillful and technically sound. His contributions to ophthalmic literature showed originality, careful preparation, and a thorough knowledge of his subject. An enthusiastic and a forceful speaker, he was a frequent and popular guest at society and post-graduate meetings where his friendliness and cordiality made many friends.

One of Dr. Clay's major interests was the underprivileged in the clinics at Grady Hospital and at his plantation locality, Walnut Grove; here, he gave unstintedly for hospitalization and education at his own expense. He loved outdoor life and sports, was an excellent golfer and a good fisherman. His hobby and avocation

was his pride in the cattle farm where his fine herd of polled-Hereford cattle thrived. At the time of his death, his farm lands were becoming a model for soil conservation and diversification.

In 1915, Dr. Clay married Eleanor Hall Solomon of Macon, Georgia, who predeceased him by several years. He is survived by his two children, Mrs. Lawson Peel Calhoun, of Atlanta, and Grady Clay, Jr., of Louisville, Kentucky, and by three grandchildren. He was a staunch member of the Methodist faith and the patron of his county church at Walnut Grove.

Those of us who worked by his side loved him, knew his worth as a friend, physician, teacher, and humanitarian. His death in the prime of his life is an irreparable loss, leaving a niche that cannot be well filled.

J. Mason Baird.

BOOK REVIEWS

DIE ERKRANKUNGEN DES AUGENHINTERGRUNDES (DISEASES OF THE EYEGROUND). By Prof. Dr. Adalbert Fuchs. Vienna, Austria, Franz Deuticke, 1943. 300 pages, 66 text illustrations, 44 color plates; German language (only a few copies are available at present).

Material for this exquisitely illustrated and concisely written book was collected during the two decades of the author's intensive activities of teaching, research, and consultations at the University of Vienna. He gives a clear description of the essential findings necessary for correct diagnosis of the common, as well as the rare, diseases of the ocular fundus and emphasizes their relation, if such exists, with the other medical specialties.

One of the best points of the book in the reviewer's opinion is the juxta position of clinical and histopathologic find-

ings, without detailed, nonessential histologic descriptions, creating an indelible association in the reader's mind between the clinical phenomena and the underlying pathologic processes. Nineteen of the 44 color plates are histopathologic illustrations, placed in such a way as to make correlation with the clinical condition extremely simple. The material of the entire book is arranged so well that ease of orientation is one of its most pleasant features. A short clinical history contained in the discussion of each colored illustration adds to the liveliness of presentation.

The book was written during the years 1941 and 1942, under great mental, emotional, and physical stress produced by the war, and Professor Fuchs is to be congratulated upon being able to create this masterpiece under such adverse conditions.

The paper of the book and the plates are of excellent, undoubtedly prewar, quality.

Our sincere congratulations go to Professor Fuchs with the best wishes for his future and that of his beautiful book.

Bertha A. Klien.

PHYSIOLOGIE OCULAIRE CLINIQUE. By A. Magitot. Paris, France, Masson & Cie, 1946. Stiff paper covers, 457 pages, 235 illustrations. Price not stated.

Evidently expecting the book to speak for itself, Magitot has dispensed with preliminary preface and introduction. The volume, well printed, well organized, and very readable, is apparently designed for the beginner in ophthalmology. An author

index is lacking, and the bibliography is scanty, inaccurate, and not closely related to the material developed. The seasoned student will miss the assimilation of the latest research, the careful documentation, the encyclopedic detail, and the interpretive insight that so brilliantly characterize Duke-Elder's textbook. Although Magitot, in his earlier chapters, favors unduly many tenuous theories of a previous decade, his treatment of photochemistry is refreshingly different and, surprisingly, includes the latest researches of von Studnitz from Pflüger's Archiv of 1943, in which the iodopsin of Wald is shown actually to consist of three carotenoid complexes homologous to the tripartite system of cone-oil globules found in many birds and reptiles.

In every section, Magitot features an excellent discussion of comparative physiology, and fortunately his stimulating presentation is not relegated to fine print. The author's own numerous researches receive only brief mention but contribute much by giving the volume a personal and authentic flavor.

This book was written under difficult circumstances. The author was in hiding in the south of France, under an assumed name, ignorant of the health and welfare of his family and the state of his property. The liberation of France permitted him to return to Paris where he was united with his family but where, too, he found that the Nazis had ravished his house and library. It is, therefore, all the more remarkable that this excellent work could appear at all.

James E. Lebensohn.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |

GENERAL METHODS OF DIAGNOSIS

Hughes, W. L. and Cole, J. G. **Technical uses of air in ophthalmology.** Arch. of Ophth., 1946, v. 35, May, pp. 525-540.

This very practical and excellently arranged article should be read in full. The injection of air into Tenon's capsule helps in localizing intraocular foreign bodies inside or outside the eyeball.

In surgical procedures air has been found of value in several ways. In cases of recent laceration of the cornea with incarceration of iris or lens capsule in the wound, mattress corneal sutures are so placed that an air-tight closure of the wound is obtained.

Anterior synechias are apt to recur after the simple incision of the band. Air forms the ideal substance for prevention. A special knife has been constructed, similar to the goniotomy knife, but with a longer blade, with which it is possible to aspirate the aqueous and insert as much air as is

required without removing the knife from the anterior chamber.

Frequently, air can be used after dissection of a secondary membrane or after iridotomy. In two patients, after intracapsular cataract extraction, a mound of vitreous protruded through the pupil. The vitreous was separated from the cornea with a suitable curved iris repositor inserted obliquely at the limbus (vitreodialysis) and air was injected to maintain the separation until the aqueous reformed.

As a final step in cataract extraction, injection of air into the anterior chamber helps to prevent incarceration of tissue in the wound.

In a trephine operation for glaucoma, air injected into the anterior chamber provides a space between the iris-lens diaphragm and the cornea, and some of the air passes out of the trephine opening under the conjunctival flap. Here it provides at least a temporary space by separation of the conjunctival flap from the underlying sclera. In the delayed formation of the anterior chamber after trephination or opera-

tion for cataract, air has been injected into the anterior chamber as an aid in its reformation.

Goniotomy, introduced by Barkan for deep chamber glaucoma, has gained only moderate acceptance because of the difficulty attending the manipulation of the heavy contact glass and the knife at the same time. With the technic that is described it is possible to perform goniotomy in glaucomatous eyes with a shallow anterior chamber, as well as in those with a wide angle.

No contact glass is used. It was demonstrated by animal experimentation that a distinct view of the anterior chamber could be obtained if air was substituted for the aqueous. Work on rabbits and on three human eyes is reported.

Koster, in 1902, used air in the anterior chamber as a therapeutic aid in cases of tuberculous iridocyclitis and keratitis. The authors have had no experience with this use of air.

In the operation for detachment of the retina, many authors have described injection of air into the vitreous with the idea of forcing the retina against the choroid.

The injection of air makes a shallow anterior chamber readily accessible to direct inspection with the slit lamp. Diagnostically the injection of air helps to decide whether a shallow chamber is due to an actual increase of vitreous or lens or to vascular congestion of the choroid. It is interesting to speculate on the diagnostic and therapeutic use of various gases that might be used to deter or combat bacterial growth or otherwise affect abnormal intraocular conditions.

THERAPEUTICS AND OPERATIONS

Blok, C. J. *Alkaline eyedrops and their stability*. *Ophthalmologica*, 1944, v. 108, Oct.-Nov., pp. 217-223.

Alkaline eyedrops are active in lower concentration because of better penetration. The stability of such solutions was investigated from a chemical and pharmacologic standpoint. Pilocarpine in boric acid solution showed practically unlimited stability, while alkaline pilocarpine solutions should not be kept longer than six weeks. Alkaline solutions of atropine, homatropine, and scopolamine are much less stable and can be used for only three weeks. Boric acid is to be avoided in the latter solutions. The author recommends the addition of 0.03 percent Nipazol or one drop of chloroform per 10 c.c. of solution for better conservation. Three sample prescriptions for pilocarpine, atropine, and scopolamine are given. (Literature.)

Max Hirschfelder.

Cutler, N. L. A basket type implant for use after enucleation. *Arch. of Ophth.*, 1946, v. 35, Feb., pp. 71-83. (See Section 13, Eyeball and orbit.)

Danielson, R. W., and Long, J. C. A method of evisceration of the eyeball. *Amer. Jour. Ophth.*, 1946, v. 29, July, pp. 859-861. (4 figures, references.)

Dubois-Poulsen, A. Penicillin in ophthalmology. *Ann. d'Ocul.*, 1945, v. 178, Dec., pp. 533-555.

The indications and contraindica-

tions of penicillin are now becoming apparent. The tolerance of different tissues varies widely. In the aqueous and cerebrospinal fluid lymphocytosis and fibrogenesis appear as a manifestation of aseptic inflammatory reaction. The therapeutic dose here varies between 200-1,000 units in 0.2 c.c. normal saline solution. The vitreous tolerates approximately 100 units. External applications and instillation of strong solutions have been followed by corneal desquamation. Allergy, though rare, may be local or general, and when it occurs local treatment must be discontinued. Local ocular instillations should be made every two hours during the day and every three hours during the night. The best average strength is 1,000 units per c.c. In severe corneal ulceration penicillin crystals have been applied directly to the wound. The intramuscular or intravenous use is less effective in ocular lesions than the subconjunctival injection of 5,000 units in 1 c.c. of 2-percent procain solution. In iritis, iridocyclitis, and choroiditis, penicillin is of questionable value. This may be owing to the character of the causative organism, the allergic character of the ocular reaction, or to other causes not yet determined. The conjunctival infections with staphylococcus, pneumococcus, the Morax diplobacillus, and the inclusion body infection of the new born, respond to penicillin. Trachoma is apparently not affected by penicillin as much as by sulphonamides. Corneal infections caused by penicillin-sensitive organisms are best treated by subconjunctival injections. In postoperative infection penicillin should be promptly used subconjunctivally or in the anterior chamber, and by local instillation. The eye should be left unbandaged and open as much as possible. The respec-

tive indications of penicillin and the sulphonamides have not yet been established. The report supplements another on this subject published earlier in this Journal (*Ann. d'Ocul.*, 1945, v. 178, March, pp. 81). Numerous illustrative cases are presented.

Gibson, A., and Carlisle, J. M. **Industrial first aid in chemical injuries of the eye.** *Sight-Saving Review*, 1945, v. 15, Winter, pp. 220-228.

Immediately after a chemical injury, the patient's eye should be flushed with water at the plant Medical Department. The contents of the conjunctival sac is then tested for its reaction with indicator paper. A local anaesthetic is applied to the eyeball, the lids and conjunctiva are thoroughly cleansed, the cornea is stained with fluorescein, so that these tissues may be examined for abrasions, foreign bodies, lacerations, and chemical burns. Treatment for burns consists of cold compresses, local anesthetics, liberal quantities of penicillin ointment, eye pads, and atropine when needed. For alkali burns, the irrigation should be continued until the secretion remains neutral in reaction. Adhesions should be looked for twice daily.

Jones, C. C. The use of penicillin in diseases of the eye, ear, nose and throat. *J. Iowa M. Soc.*, 1946, v. 36, May, pp. 193-194.

The inhibitory action of penicillin affects the staphylococcus aureus, hemolytic streptococcus, pneumococcus, gonococcus, and meningococcus. Penicillin inhibits the metabolism of the intracellular enzymes of these organisms. Normal saline solution, or certain buffers are the vehicles of choice. An aqueous solution is said to lose 10 percent of its potency every twenty-four hours at five degrees centigrade.

Penicillin is compatible with all drugs that are used in the external diseases of the eye except adrenalin. It has been used to good advantage (1,000 units per c.c.) in dacryocystitis. Penicillin ointment of the same concentration, instilled every four hours, gives better results than the solution in acute catarrhal infectious conjunctivitis. According to O'Brien, penicillin ointment, 1,000 units per gram, is more effective than 5-percent sulfathiazole when combined with meibomian massage and staphylococcus toxoid desensitization in chronic blepharitis and conjunctivitis. Ulcers of the cornea that are resistant to usual therapy have responded to subconjunctival injections of one half c.c. of penicillin, 1,000 units per c.c. twice daily. The procedure is painful and requires local anaesthesia.

In iontophoresis, a solution of 500

units per c.c. is used for three minutes with a current strength of two milliamperes. I. E. Gaynon.

Law, T. B. Penicillin in preoperative and postoperative ophthalmic surgery. *M. J. Australia*, 1946, v. 1, March 30, p. 442.

A violent reaction resembling early panophthalmitis occurred in a patient after a cataract extraction. Intensive penicillin therapy was instituted immediately. The drug was given intramuscularly (100,000 units in 6 hours), and was also instilled into the conjunctival sac every hour. Within eight hours the eye cleared remarkably and there was uneventful recovery.

The second patient, a man aged 75 years, had a mature cataract, a marked chronic conjunctivitis with muco-purulent discharge, and a history of chronic purulent sinusitis. Repeated conjunctival cultures showed as many as 30 colonies of staphylococcus aureus. Penicillin was instilled in the conjunctival sac every hour for 10 hours, when the sac was found to be sterile. The tear sac was removed despite the fact that it was free from discharge. The cataract was removed after five hourly instillations of penicillin solution and there was uneventful recovery. On departure from the hospital two weeks later 30 colonies of staphylococcus aureus were found in cultures.

Schmid, A. E. *The distribution of Irgamid in the tissues and fluids of the eyeball*. *Ophthalmologica*, 1943, v. 106, Nov.-Dec., pp. 289-300.

Irgamid is a sulfanilamide derivative that the author used in experiments on young rabbits.

The Irgamid was used locally in the form of a powder or of a 15-percent ointment, was introduced through a stomach-tube or was injected in a 20-percent aqueous solution into the marginal vein of the ear.

The eyeballs were examined immediately after the death of the animal and the drug content of the individual ocular structures was determined by the

method of Pulver. The concentrations varied considerably with the method and time of administration. The variations from individual to individual were unessential.

Local administration gives a remarkable concentration in the anterior chamber and in the strongly vascularized tissues of the eyeball. This concentration is greater, when the corneal epithelium is damaged, in all tissues except the lens. In the lens the drug concentration, which is usually small, is even smaller in corneal erosions. The concentrations after administration in the powdered form rise rapidly and are rather high. They are lower and of longer duration after using the ointment. Administration four times per day results in the greatest concentration.

In peroral administration the maximum concentration was attained after 10 hours. The conjunctiva, the vitreous, and especially the choroid and retina manifested high concentration and slow elimination.

Intravenous application produced a rapid concentration of the drug in all ocular tissues and fluids, particularly in the vitreous. (9 tables and curves, references.)

Struble, G. C. and Bellows, J. G. Contact eye cup for corneal baths with solutions of penicillin. *Arch. of Ophth.*, 1946, v. 35, Feb., pp. 173-175.

Simple instillation of penicillin eye drops will effect a prompt cure of the acute inflammatory diseases of the conjunctiva caused by penicillin-sensitive organisms. Simple instillation is not adequate in corneal ulcers, particularly if the deep layers of the cornea are involved. A special contact eye cup is described which is made of clear acrylic material. It can be fitted over the eyeball and a small flat handle projects between the lids. The cup has two holes, one for filling it and the other for the escape of air. With the patient in a sitting or reclining position and the eye anesthetized, the cup is inserted and filled with penicillin solution by means of a syringe. The cup is then left in place for one-half to one hour. There is no loss of solution through the lacrimal apparatus nor is there dilution by the tears. The transparent cup permits view of the anterior segment of the globe and the level of the penicillin solution at all times. The contact cup fits both eyes. Illustrated.

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Angius, T. Experimental studies of night blindness. *Rassegna Ital. d'Ottal.*, 1946, v. 15, no. 1 and 2, p. 11.

A group of 51 healthy men between 18 and 21 years of age were studied daily for several weeks to determine the effects of vitamin A upon their light threshold. It was concluded that vitamin A has a specific action, especially to increase the perception of form. The action is either catalytic, favoring the power of fatigued tissue to recuperate, or an augmentation of vitamins to rebuild the visual purple. Vitamin A is therefore indicated in those individuals who need to lower their light threshold and in those who are unduly fatigued or exposed to intense light. (6 figures, 1 table.)

Bateman, Eric. The Cantonnet system from the viewpoint of general psychology. *The Optician*, 1946, v. III, Feb. 15, pp. 46-47.

The unilateral repression of an image can be likened to the repression that occurs in the mind when faced with a situation which it finds intolerable. The eye deviates to displace an offending image and the mind at a higher level represses the image, and represses it still more at the macula to keep the eye from turning back. A discussion is given of the ego, the subconscious level, and the conscious level. Apply-

ing the principles of psychology, the treatment consists of a careful refraction, correction of the amblyopia as much as possible, exercises to overcome repression or, as Cantonnet calls it, neutralization, and the development of simultaneous and stereoscopic vision.

Dudragne, R. A. **Physiologic amplitude of accommodation and false accommodation of the aphakic eye.** *Ann. d'Ocul.*, 1945, v. 178, Sept.-Oct., pp. 377-398, 441-452.

The subject is discussed under the following headings: correction of anetropia; corrected accommodation in ametropia; complete correction of the eye; depth of the field of the eye; spheric aberration of the eye; punctum remotum and pupillary opening; physiologic accommodation of the aphakic eye; experimental studies.

The mathematical analysis of each topic is presented in detail. Increased size of the pupil in twilight may increase the focal power of the eye as much as two diopters. Some of the fac-

tors involved in accommodation are best studied in the aphakic eye in which a false accommodation may be as great as five diopters. Among the factors that bring it about are: the distance of correcting lenses from the cornea; astigmatism that is caused by angulation of correcting lenses; unequal focal power of different sectors of the cornea; occupational familiarity with the interpretation of images; pressure on the eye by the lids; depth of the visual field; and spheric aberration of the eye.

Gonzales, J. B. **Dark adaptation in pregnancy.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Feb., pp. 120-128.

Forty women in the second half of pregnancy were examined with the Birch-Hirschfeld adaptometer. Their adaptation curves, while within physiologic limits, are somewhat inferior to the normal controls. Eight percent of the patients had definitely subnormal adaptation curves, but none of them had subjective hemeralopia. The adaptation of women on diets adequate in vitamin A were no different from those on inadequate diets. The adaptation curves show no variation during the months of the second half of pregnancy. (Adaptation curves.)

Ray K. Daily.

Göthlin, G. F. **Inhibitory processes in the normal mechanism of the color sense.** *Ophthalmologica*, 1944, v. 107, March-Apr., pp. 158-177.

From his experiments the author concludes that the fundamental color sensations of man are red, green, and blue, not violet. From observations when mixing complementary colors in different proportions, and from the existence of negative ordinates in Maxwell's and Wright's graphically ex-

pressed measurements of three-color synthesis of spectral monochromatic colors, the author infers that each excitatory impulse that proceeds from the color receptors is accompanied by an inhibitory nerve impulse to the substratum of its complementary color. It is assumed that the sensation of yellow results from a central coordination of impulses which come from the red and green receptors. This synthetic yellow plus fundamental blue, if the impulses are equally strong, give the sensation of white. The author expresses the opinion that the negative afterimage has its origin in elements that were inhibited during the presentation of the positive color and spontaneously come into a state of excitation after the positive color disappears. The differences between the author's hypothesis and the theories of Young-Helmholtz and of Hering are discussed. (Bibliography.) Max Hirschfelder.

Göthlin, G. F. An analysis of the perception defect in published and spectroscopically investigated cases of congenital tritanopia. *Acta Ophth.*, 1943, v. 21, pt. 1-2, pp. 88-96.

An analysis of the published cases of congenital yellow-blue blindness shows that they form two different categories. One group of blue-blind subjects have color sensations from the violet part of the spectrum. The second group is both violet and blue blind, and also has a simultaneous weakening of perception of long-wave red. This later group therefore comprises the pure cases of tritanopia. One of the two typical tritanopic subjects examined saw spectral violet as pale red, and the other as red dotted with small black spots. These data indicate that violet is a product of simultaneous stimulation of blue and red. The fact that in the ab-

sence of blue perception violet takes on the character of red gives further support to the author's contention that violet is a product of simultaneous fundamental sensations of blue and red.

Ray K. Daily.

Göthlin, G. F. Participation of central inhibitory processes in the synthesis of color sensations. A working hypothesis. *Acta Ophth.*, 1943, v. 21, pts. 1-2, pp. 75-87.

With the help of a double-balance model, Göthlin outlines his theory of color perception, which assumes that every impulse from retinal receptors for a color sensation is always combined with a certain degree of central inhibition of the complementary color in the same area. According to his theory the sensation of white is developed in two stages; in the first a balance between impulses for red and green produces yellow; in the second yellow and blue produce white. This theory, contrary to the Young-Helmholtz theory considers blue as a fundamental color, and differs from Hering's theory in assuming that yellow is the result of central synthesis of green and red, and denying that red and green are complementary colors. For experimental evidence supporting his theory reference is made to the *Journ. of Phys.* v. 57, and to the *Handlingar of the Swedish Academy of Science*, Ser. 14, v. 20: 7.

Ray K. Daily.

Hardy, L. H., Rand, G. and Rittler, M. C. Tests for detection and analysis of color blindness. *Arch. of Ophth.*, 1946, v. 35, Feb., pp. 109-119.

This is a report of data collected in the study of 106 persons with defective color vision of varying types and amounts by means of various editions of the Ishihara test for color blindness.

A comparison of the average scores and the range of scores for the different types of deficiency in color vision does not show notable differences in the fifth, seventh and ninth (British reprint) editions of the Ishihara test. Properly administered, the three editions of the test afford a good rough device for screening persons with defective from persons with normal color vision if a performance score of 60 is taken as the critical score. A critical score cannot be established for the 10 Ishihara plates reproduced in the American Optical Company's test. Tested with this group of plates, some subjects with defective color vision passed all the plates and some with low normal color vision passed only six of the plates.

John C. Long.

Hartridge, H. Recent advances in the physiology of vision. *Brit. M. J.*, 1946, April 27th, pp. 637-638.

Goldman and Hagan measured the length of the eyeball by passing a beam of X rays through a slit in a stout metal plate. A narrow ray is produced that falls on the observer's dark adapted eye at right angles to its optic axis. A beam of light is seen concentric with the fovea. As the beam moves backward in the eye, it becomes narrowed to a point and coincides with the most posterior part of the retina. The beam is then moved forward until it coincides with the anterior part of the cornea. The movement is carefully measured. Total refraction of the eye is measured by the following procedure. Two narrow beams, five millimeters apart, are projected in at the front of the eye just below the line of sight. Two narrow beams are projected by an optical lantern on a screen and are adjusted until they coincide with the X-ray images. The distances are care-

fully measured. Total refraction in diopters equals 1000 times distance between lantern beams divided by screen distance times the distance between X rays. Their mean values are as follows: length of eyeball equals 24.05 millimeters; total refraction equals 58.75 diopters; nodal distance equals 17.02 millimeters; posterior focal distance equals 22.73 millimeters.

Granit's work on the micro-electrode experiments depends upon the principle that when a sensory nerve is stimulated, it undergoes a change of electrical potential. The retina of an animal is exposed and a single optic nerve fiber is stimulated and the change in potential measured. He found eight types of receptors. Type 1 is the dominator; the remaining seven are called modulators. There is one modulator for orange, one for yellow, three types for different shades of green, and two for blue.

Using the Landolt ring test, Schlaer found little difference in the visual acuity when lights of different colors were compared to white. An experiment is also described wherein the spurious colors of chromatic aberration are eliminated by a nervous process called the antichromatic response.

I. E. Gaynon.

Hylkema, B. S. Examination of the visual field by determining the fusion frequency. *Acta Ophth.*, 1942, v. 20, pt. 2, pp. 181-193.

This investigation was made by arranging the test-field in the form of a campimeter, and taking the fusion frequency at various areas in the field. The graphically recorded data show that there is a region of low fusion frequency in the vicinity of the blind spot. The fusion frequency is lower in the upper than in the lower part of the field. The highest figure is found nasal-

ly and the lowest temporally. In normal binocular vision the temporal downward area in the visual field of one eye corresponds to the nasal downward area of the contralateral eye. Therefore, when an object is less than 30 degrees from the fixation point, the function of the eye, which fixates the object nasally, must predominate. If the object lies to the right, the left eye predominates. When the object is farther in the periphery, the eye on the same side takes over the task. The fusion frequency test demonstrates more effectively than any other test the predominance of one half of the visual field over the other. Ray K. Daily.

Hylkema, B. S. **Fusion frequency with intermittent light under various circumstances.** *Acta Ophth.*, 1942, v. 20, pt. 2, pp. 159-180.

This investigation on the fusion frequency discusses the frequency at high light intensities, and with interaction. It was found that the fusion frequency peak is formed under an illumination of 200 to 800 candle power per square meter. The author suggests that this light intensity might represent the optimum illumination for visual functioning, and serve in the evaluation of lighting conditions. After reaching this peak, further increase in light intensity results in a drop in the fusion frequency; at the state of adaptation at which the fusion frequency curve drops signs of dazzling appear. The diminished color sensitivity associated with dazzling and the lowered fusion frequency point to a temporarily impaired visual function.

Interaction was investigated with the use of two or four intermittently illuminated test fields, synchronously or in opposing phases. The charted results show that interaction is stronger

in the periphery than in the center; it is effective across a longer distance in the periphery, up to five degrees, which corresponds to 0.5 millimeters on the retina. The experiments show that in addition to the light intensity, the size of the illuminated area is also a factor in the fusion frequency. An attempt was made to ascertain the degree of cerebral influence on the fusion frequency by making observations monocularly and binocularly. The figures obtained with one or both eyes differ but little from each other. This is interpreted to indicate that by far the larger share in this process is taken by the retina, and that the cortical influence is slight. Light intensity produces its effect largely in the retina. Area effect and interaction is ascribed to the associative nervous system of the retina. The state of adaptation is determined by the outer layer of the retina, and perhaps also by the central nervous system. Local adaptation that occurs with a long exposure is largely a cerebral process. Ray K. Daily.

Khan, N. E. **Vitamin A and night vision.** *Indian Med. Gazette*, 1945, v. 80, Dec., p. 608.

Dark adaptation studies were made in 190 British Military Personnel and 1,090 Indian soldiers. Sankaran's photometer showed defective dark adaptation in 14 percent of the British and 29.2 percent of the Indian soldiers. Thirty-eight (3.5 percent) of the latter complained of night blindness although there were only two who could not see in the dark. This condition therefore is not as common as is supposed. All but one of the 26 Indians treated with vitamized oil developed normal dark adaptation within two weeks.

Recent data on Vitamin A are discussed. Greater use of carrots and

greens of the spinach type, such as saks, is suggested to improve Indian nutrition.

F. M. Crage.

Mann, Ida, and Sharpley, F. W. The normal visual (rod) field of the dark adapted eye. *Jour. Physiol.*, 1946, v. 104, April 15, pp. 384-391.

The authors tested one eye of each of 47 subjects after dark adaptation. They used a perimeter of 33-cm. radius, a radium target below the cone threshold as stimulus, and a red light for fixation point. The angular radius, that is the angular distance from the center of the plotted field, was calculated as an average of the plotted values of the 24 meridians at 15-degree intervals. The size of field seemed to decrease with increase in age of subject. The fields differed considerably in shape, but the area as expressed in terms of its mean angular radius was fairly constant. Low errors of refraction apparently were negligible. (2 tables, 2 figures, references.)

Bennett W. Muir.

Martin, D. H. H. Some refinements in cross cylinder technique. *The Optician*, v. 111, May 24, 1946, p. 330.

The writer uses the cross cylinder because it puts less demand on the intelligence of the patient, is more rapid, and blends well with the objective examination.

Certain test letters are recommended for the testing of the axis. For estimating axis direction at approximately 90 or 180 degrees, he recommends the letters E, F, H, L, and T; to estimate axis direction at 45 or 135 degrees the letters V, W, X, and Y, and to test cylinder power in the same positions the letters E, F, H, L, and T.

I. E. Gaynon.

Matteucci, P. Quantitative and qualitative perimetric studies with monochromatic and white targets. *Rassegna Ital., d'Ottal.*, 1946, v. 15, no. 1 and 2, p. 26.

Using monochromatic and white targets of equal subjective brilliance revealed findings quite diverse from those of previous investigators. The threshold of light was determined in each subject by photometric measurements. With equality of size, saturation, and brilliance of the target used, and with minimal variations of illumination and of adaptation, important modifications of the peripheral limits for colors were found.

Varying degrees of sensibility of the retina for a single color and other factors not easily controllable make it difficult to define exactly the peripheral limits for colors. The author expresses doubt as to the utility of clinical perimetry with colors. (1 figure.)

Eugene M. Blade.

Parker, F. W. Studies on dark adaptation in military personnel complaining of "night blindness." *Arch. of Ophth.*, 1946, v. 35, May, pp. 555-571.

A fairly common complaint of patients seen by the ophthalmologic service at the front is poor night vision.

Sixty-six patients were examined with a Nagel adaptometer for determination of dark adaptation. Careful ophthalmologic examinations were made, and neuropsychiatric consultation was secured when indicated. Thirty-nine patients of the group complained of moderate to extreme night blindness. Fourteen had no ocular complaints, and 13 were patients with hepatitis. Of the 14 patients with no ocular complaints, all showed normal adaptation curves. Of the 39 patients

who complained of night blindness, 5 with moderate complaints showed normal dark adaptation, and three of these had more than 1.50 D. of astigmatism. For six others with normal readings but severe complaints detailed histories revealed some incident that had caused the patient to believe that his night vision was inadequate. The remaining 28 of the 39 patients had initial low readings for dark adaptation. No cause for this could be found in 5 patients, and these men were considered to have true simple hemeralopia; 4 had a pathologic condition of the fundus; 5 patients proved to be malingering, and 14 were psychoneurotic. Of the 19 patients who were malingerers or psychoneurotic, 11 had corrected vision of 20/40 or less, and 12 had refractive errors of above 1.50 D.

A test for malingering is described which utilizes optokinetic nystagmus.

Six patients with chronic disease of the liver showed subnormal dark adaptation. Three of these persons were given oral vitamin A therapy, with pronounced improvement. Six patients with infectious hepatitis, whose disease did not become chronic and whose hospitalization did not exceed 15 weeks, showed normal dark adaptation curves.

R. W. Danielson.

Pescatore, C. **The operation of Fukala in high myopia.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, no. 1 and 2, p. 48.

The author reports six cases of high myopia in which clear lenses were removed by aspiration. He concludes that the operation is not free from severe postoperative complications, but that the improvement in vision warrants the risks. The best time for operation is between 8 and 20 years of age, and the operation is most successful in eyes

with about 20 diopters of myopia. Fundus changes are not a contraindication to the operation and discission of the capsule is usually required.

Eugene M. Blake.

Pincus, M. H. **Unaided visual acuities correlated with refractive errors.** *Amer. Jour. Ophth.*, 1946, v. 29, July, pp. 853-858. (2 tables, reference.)

Rand, G. **Relation between illumination and visual efficiency.** *Arch. of Ophth.*, 1946, v. 35, May, pp. 509-513.

Rand quotes Weston's investigation which was undertaken to test the value of a method suggested by Beutell for determining the level of illumination required for the efficient performance of work that involves visual discrimination. The method is based on the proposition that the illumination required for any visual task, as compared with the simplest possible task, depends on certain conditions adversely affecting its performance, that these conditions can be defined, and that if the relationship can be ascertained between each of the conditions and the illumination required to compensate for it, then the illumination suitable for the performance of the task ought to be capable of actual computation.

A discussion of the various factors involved in illumination and visual efficiency is given.

From a practical point of view, Weston's studies and those of Ferree and Rand show that level of illumination cannot compensate entirely for the adverse conditions of small size of detail and poor contrast in the work. When the task is such that these factors cannot be improved the level of illumination should be made as high as is compatible with other factors of good

lighting, such as freedom from high brightness and high brightness ratios in the field of view. In most cases of this type it is likely that the most favorable illumination will be furnished by a good general level of background illumination, free from glare and high brightness ratios, supplemented by local lighting of the immediate task, the source of which must be well shielded from the eyes of the worker.

R. W. Danielson.

Redlich, F. C., Callahan, A. and Mendelson, R. H. **Electroencephalographic change after eye opening and visual stimulation.** *Yale J. Biol. and Med.*, 1946, v. 18, May, pp. 367-376.

In a study of 100 subjects, the electroencephalographic changes upon eye opening, which were not uniform, were characterized mainly by a decrease of amplitude and less by increase in frequency of the occipital rhythm. These changes were usually reversed by closing the eye. Three patients with bilateral blindness showed no changes. The effect on the electroencephalogram caused by the opening and closing of the eye does not permit a consistently valid differentiation between true and hysterical, and malingered blindness. (1 table, 4 figures, references.)

Rocha, Hilton. **Cycloplegine (Benzoil-diethyl-aminol-ethanol).** *Rev. Brasileira de Oft.*, 1946, 4th yr., June, no. 4, pp. 297-301.

This substance is one of those recently proposed as substitutes for homatropine, to which they are considered superior in regard to brevity of action and of speedy return to normal. Parenthetically, credit is given to Swan and White for their studies of di-n-butylcarbaminolcholine. The author

concludes that cycloplegine is "on the right track," and that in certain special aspects it is very superior to homatropine and atropine, although he admits that it shows a striking tendency to cause lacrimation, which may interfere with the usefulness of the drug.

Sorensen, S. K. **Lenticular astigmatism, designated as the difference between total and corneal astigmatism, illustrated by an examination of its variations with age.** *Acta Ophth.*, 1944, v. 22, pt. 4, pp. 341-385.

In this laboratory investigation the corneal astigmatism was measured with the ophthalmometer and total astigmatism with the refractometer. The graphically presented data and the calculations based on them lead to the following conclusions. Corneal astigmatism is the most important factor in total astigmatism. In corneal astigmatism against the rule the total astigmatism is against the rule and greater than the corneal astigmatism. In the absence of corneal astigmatism a small degree of total astigmatism against the rule is generally present. With weak corneal astigmatism with the rule one usually finds a total weak astigmatism against the rule or no astigmatism at all. In moderately high corneal astigmatism with the rule, the total astigmatism is also with the rule but lower than the corneal. In very high corneal astigmatism with the rule one often finds a high total astigmatism. The total astigmatism shifts with age so as to bring an increased astigmatism against the rule. The corneal astigmatism varies within wide limits. In children and young people 0.75 D. of astigmatism with the rule may be considered physiologic and 0.50-0.75 D. is physiologic in older persons. At 50 to

60 years of age no astigmatism or very weak corneal astigmatism with or against the rule is physiologic. In the aged weak astigmatism against the rule is most frequent. Thus it is seen that the senile corneal changes direct the corneal astigmatism against the rule. Lenticular astigmatism is very frequent; usually it is very weak, but it may reach considerable proportions. The strongest lenticular astigmatism found was 2.00 D. Lenticular astigmatism is usually against the rule. In children and young people 0.75 D. of lenticular astigmatism against the rule is physiologic. In older people 0.50 D. lenticular astigmatism against the rule is common. In the aged lenticular astigmatism usually does not exceed 0.25-0.50 D. against the rule. Weak degrees of corneal astigmatism with the rule are usually compensated by lenticular astigmatism against the rule. Moderately high corneal astigmatism with the rule is partially neutralized by lenticular astigmatism against the rule. In high corneal astigmatism the lenticular astigmatism is usually of the same type. Corneal astigmatism against the rule is usually associated with lenticular astigmatism against the rule. With age the lenticular changes modify the refraction of the lens in the direction of astigmatism with the rule. Lenticular astigmatism is very variable and in determining refraction the total astigmatism should be considered. (13 graphs.)

Ten Doesschate, J. **The relation between visual acuity and the differential threshold of brightness sensation.** *Ophthalmologica*, 1944, v. 108, Oct.-Nov., pp. 187-209.

The differential threshold in comparing two brightnesses B and B' is determined under such conditions that the brightness B fills the whole visual field (inside wall of a globe) while B' is being observed in the shape of a circular testfield (visual-angle g) with foveal fixation. B' is projected through an

opening in the globe on B. It is found that the differential sensitivity increases with an increase in B and with an increase of the visual angle. The stage of adaptation influences the differential sensitivity, as the differential sensitivity is diminished in an eye which is not adapted to a lesser general brightness B. It is shown that visual acuity and differential sensitivity depend in an identical way on the brightness B. The results of the experiments are in accordance with recent calculations of de Vries, which take into account the statistical fluctuations in the number of light quanta, which are projected on the different retinal regions. Max Hirschfelder.

Wartenberg, R. **Associated movements in the oculomotor and facial muscles.** Arch. Neurol. and Psychiat., 1946, v. 55, May, pp. 439-488.

Based upon the study of four patients, a critical analysis is presented of the commonly accepted hypothesis that associated movements in the territory of the third nerve are due to a misdirection of regenerating fibers. It is suggested that the release phenomenon of Hughlings Jackson more accurately explains these phenomena. After incomplete recovery from third nerve paralysis abnormal phenomena occur, such as the retraction of the upper lid with downward rotation of the globe (pseudo-Graefe phenomenon), and pathologic vasomotor and secretory phenomena. The author gives many reasons why the misdirection theory is untenable. The phenomenon occurs when there has been no trauma to the nerve, or before regeneration could have occurred, or as a congenital anomaly. Once established it is present for life. Associated movements are compared with the symptoms of py-

ramidal tract lesions, and are found to be similar. The author says "The hypothesis of released phenomenon propounded here, though it may appear somewhat hazardous, seems to be a workable, expandable one, capable of providing further supporting argumentation." (Photographs, references.)

Bertotto, E. V. **Congenital paralysis of the lateral rectus and melanosis bulbi.** Anales Argentinos de Oft., 1945, v. 6, Apr.-May-June, pp. 60-62.

The left eye of an 18-year-old youth had a visual acuity of 6/6, the skin of the lids and the sclera were discolored a slaty gray, the iris was heterochromic, and the lateral rectus was paralyzed, though no diplopia was present. The fundus was normal. The author offers no treatment, and gives a good prognosis. Edward Saskin.

Broendstrup, Poul. **The squinting position of weak-sighted eyes.** Acta Ophth., 1944, v. 22, pt. 4, pp. 386-393.

The material of this investigation comprises 162 patients with impairment of vision in one eye, and normal

visual acuity in the other. The cause of the impaired vision was spontaneous or traumatic unilateral cataract. Most eyes had been operated upon and were aphakic. The material was divided into 3 groups: congenital cataracts, cataracts acquired before the tenth year of life, and those acquired after the age of 11 years. The data of group one indicate that convergence is the position of rest in early childhood, and divergence dominates the picture later. The data of the second group indicate that the older the individual is at the onset of the cataract, and the longer the amblyopic period, the more will divergence dominate as a position of rest. In patients affected under five years of age divergence and convergence will be equally frequent during the first 12 years. If defective vision sets in after the age of five years divergence will be the dominant position of rest. In group three divergence is the dominant position. The data show that when binocular vision is abolished because of unilateral visual impairment the axes of the eyes rarely remain parallel, and that the deviation continues to change for many years. (3 graphs.)

Foster, J., and Pemberton, E. C. **Effect of operative alterations in the height of the external rectus insertion.** *Brit. Jour. Ophth.*, 1946, v. 30, Feb., pp. 88-92.

In 26 patients who were to have surgery for strabismus, careful measurement revealed vertical phorias of varying amounts. At operation the external rectus, in addition to being advanced or recessed, was raised or lowered on the sclera. Elevation of the muscle raised the eye and lowering it depressed the eye. The results apparently justify the procedure. The measurements of the

muscle functions in each patient are presented in tabular form.

Morris Kaplan.

Gallo, L. A., and Novick, R. **Paralysis of the external rectus. Its treatment with transplants from the superior and inferior recti.** *Anales Argentinos de Oft.*, 1945, v. 6, July-Aug.-Sept., pp. 101-103.

Paralysis of the right lateral rectus muscle appeared in a girl, 19 years of age, after typhoid fever. To overcome it a 6-mm. recession of the internus was done, a temporal slip from the inferior rectus muscle and the superior rectus was attached to the insertion of the lateral rectus, and the latter muscle was advanced. Sixty degrees of abduction was achieved. (1 illustration.)

Edward Saskin.

Gibson, H. W. **The spheres of orthoptics and surgery in the treatment of strabismus.** *The Optician*, 1946, v. 111, June 21, pp. 413-415.

The primary aim of all treatment of strabismus should be the restoration of normal binocular stereoscopic vision. Orthoptic treatment alone is indicated when the ocular muscles are not affected by malformation, paralysis, or paresis. Surgery alone seldom restores binocular stereoscopic vision. It is cosmetic in effect and is used alone when conditions are unfavorable for the attainment of stereopsis. In preoperative orthoptic treatment one strives to eliminate suppression and to teach the patient to learn to use both eyes simultaneously. Post-operative orthoptic treatment ensures accurate alignment of the visual axis with the establishment of stereopsis. I. E. Gaynon.

Nordlow, V. W. **The pathogenesis and early operation of constant con-**

vergent strabismus. *Acta Ophth.*, 1945, v. 23, pt. 2, pp. 97-125.

Nordlow favors early operation, and this study contains the tabulated observations on 23 children who were operated upon early. They were in their second year or older when the strabismus was noticed. At operation the youngest patient was not quite two years old, and the oldest just over eight. The operation consisted of a bilateral partial tenotomy of the internal rectus muscles and resection of the external rectus. The author concludes that early operation cures the strabismus and leads to binocular vision in 91 percent of patients. The strabismus is believed to be a hereditary defect. (7 illustrations.)

Ray K. Daily.

Nordlow, Waldemar. The pathogenesis of convergent strabismus. *Acta Ophth.*, 1942, supplement 20, pp. 134.

The objective of this monograph is to assess the role of refraction, fusion, and mechanical factors in the pathogenesis of internal strabismus. The data obtained by an examination of 105 normal children, seven to nine years of age, 100 normal adults between 23 and 40, and 334 patients with strabismus under 40 years of age are analyzed. The examinations determined the angle of squint, the position of the visual lines, the range of motility, refraction, retinal correspondence, and range of accommodation. The history furnished data on the age at the onset of squint, the course of the strabismus, and the concurrent occurrence of disease. The findings show that normally there is no significant difference in the range of horizontal motility in children and adults. In squinters the primary angle of strabismus at 5 meters was most constant and chosen for comparative study. After the elimination of doubtful

cases, paresis appeared to be a factor in 17.5 percent. In 59.4 percent the angle of strabismus was dependent on the accommodation.

In 177 older patients with strabismus the range of ocular motility was normal in extent in both eyes, but shifted inwards. In 66 percent of these the shift corresponded with the primary angle of strabismus. In as much as the shift can be accounted for only by a mechanical abnormality, it is probable that the mechanical abnormality is also the cause of the strabismus. In 30.5 percent the shift of ocular motility was less in extent than the angle of strabismus and in 3.4 percent it was greater. In 138 patients with permanent strabismus over eight years of age 15.9 percent had normal retinal correspondence. The age at the onset of strabismus differed from that found by Smith and Worth. The frequency in this material was highest in the first year, and gradually diminished to the eighth year. In strabismus noted at birth the factors accounting for it must have been present at birth or earlier. Of 253 patients under seven years of age, 97.8 percent were hyperopic, 1.4 percent emmetropic, and 0.8 percent myopic. In 42 patients seen in their first year of life atropinization and the wearing of the refractive correction had no effect on the angle of strabismus, which indicates the action of a mechanical factor in the genesis of the squint. In 58 percent of the patients the ability to fuse appears to have existed at the onset of squint. All patients with periodic squint had a fusion faculty. Illness preceded the onset of squint in 11.8 percent of the patients; in these there is the possibility of a disturbance of fusion due to meningitis or encephalitis. The author concludes that a mechanical factor which can produce a

deviation of the visual axis even in the presence of the fusion faculty is present at the onset of permanent strabismus. In half of the cases a disturbance of fusion did not appear to be a factor. Periodic strabismus can be differentiated into two types. In one type the deviation can be attributed solely to a mechanical factor and in the other type a refractive error also plays a part. Nordlow, W. A. **An instrument for measuring the muscle resection in strabismus operations.** *Acta Ophth.*, 1944, v. 22, pt. 1, pp. 49-51.

The instrument consists of a strabismus hook calibrated in millimeters and a muscle clamp, the length of which is equal to the distance from the 0 point on the hook to its curved end. (5 illustrations.) Ray K. Daily.

Ochoa, R. G. **Anomalous congenital strabismus.** *Anales Argentinos de Oft.*, 1945, v. 6, July-Aug.-Sept., pp. 89-97.

A boy, 10 years of age is described, in whom there were bilateral exophthalmos, esotropia with deviation of the left eye, narrowing of the palpebral fissure of the left eye on adduction, and a weakness of the left lateral rectus. The author reviews several similar cases reported in the literature, and divides them into two groups: those with retraction of the globe on adduction, and those without retraction. When there is retraction there must be a pathologic derangement at the origin of the lateral rectus muscles. When there is no retraction the lesion is probably nuclear. If surgery is contemplated, it should be directed toward attaching a slip of muscle from the superior and inferior rectus muscle to the lateral rectus. (Bibliography.)

Edward Saskin.

Pascal, J. I. **Charting diplopia and muscle action.** *Amer. Jour. Ophth.*, 1946, v. 29, August, pp. 1001-1006. (5 figures.)

Scaglione, C. **Miner's nystagmus in the mines of Sardinia.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, no. 1 and 2, p. 20.

In an examination of 30,000 miners in Sardinia the author could not find a single case of miner's nystagmus. He attributes this fact to the conditions under which the laborers work, that is in the erect position, in excellent illumination and good ventilation, and without explosives. All of these factors lessen the psychopathic tendencies which tend to produce miner's nystagmus.

CONJUNCTIVA

Apin, K. **Trachoma control in Latvia.** *Klin. M. f. Augenh.*, 1943, v. 109, May-June, p. 322.

Apin reviews a campaign for the control of trachoma which he carried out in Latvia during the years 1926 to 1940. During that period of 15 years 1029 trachoma patients, or 3 percent of the total number of eye patients were included in this state-wide program. It was found that most patients did not receive effective treatment early enough. The incidence of trachoma was definitely higher in women than in men, possibly because women who take care of trachoma-infected children are more exposed to the infection. Only 36.8 percent of patients were free from complications when treatment was begun. Normal vision in both eyes was found only in 26.6 percent of the patients, and chiefly in the young. Screening of the whole population is difficult or impossible because communities are widely

scattered and the majority of the few available ophthalmologists are in Riga. It is important to discover the disease as early in life as possible. School physicians must examine all pupils for trachoma at least twice a year and industrial employees must be examined at regular intervals. The practicing physicians must check for trachoma all patients who consult them for other ailments. Persons who are exposed to trachoma are watched especially carefully. The names of patients who have trachoma must be reported.

Bhat, P. K. **Diphtheritic conjunctivitis complicating septicemia.** *The Antiseptic*, 1946, v. 42, May, pp. 317-319.

The author describes a boy, eight years of age, who had all the signs of septicemia as well as a bilateral severe conjunctivitis. A thick gray membrane covered the conjunctiva and cornea. No cultures or smears were taken, but there was an almost immediate response to diphtheria antitoxin. Twenty thousand units were injected on three consecutive days.

I. E. Gaynon.

Byrn, Willy. **Three cases of hemangioma of the subconjunctiva.** *Acta Ophth.*, 1944, v. 22, pt. 2, pp. 166-175.

Histologically one hemangioma was of the cavernous type, one simple, and the third was untreated and unavailable for microscopic examination. The literature is reviewed and the 67 reported cases analyzed as to the age of observation, localization, and microscopic structure. The data indicate that the neoplasm is mostly congenital; in rare cases trauma is a factor. The place of predilection is the inner canthus and the adjacent bulbar conjunctiva. The conjunctival angiomas have a tendency to grow into the eye muscles and into

the orbit and should therefore be removed early. (2 illustrations.)

Ray K. Daily.

Ficandt, Olaf. **A papilloma of the conjunctiva originating in the plica semilunaris.** *Acta Ophth.*, 1944, v. 22, pt. 1, pp. 44-48.

This presumably benign neoplasm, excised from a man 64 years of age, is described clinically and histologically. The variations in the structure of the neoplasm, the difference in the size of the nuclei, and the numerous mitotic figures suggested malignancy. The case illustrates the importance of histologic examination. (3 illustrations.)

Ray K. Daily.

Gartner, S. **Method for biomicroscopic study of the conjunctival blood vessels.** *Arch. of Ophth.*, 1946, v. 35, May, pp. 519-524.

The conjunctival vessels are readily available for study and provide the ophthalmologist with a unique opportunity to learn many of the details of the ocular circulation.

The conjunctival blood vessels can be examined in some detail with the usual slitlamp. However, even with the widest slit there is insufficient light, and much is lost. The slit beam is of little advantage in studying the conjunctival vessels. So much has been written of recent years concerning the value of the sharply focused slit beam of light that it seems to be going backward to remove the slit. However, conditions in the conjunctiva are very different from those in the pupillary zone. In the transparent media of the eye, the narrow focused slit beam of light is a splendid arrangement, while its illumination is near the upper limit of tolerance for most patients. However, on the conjunctiva a wider field of

illumination is advantageous, and higher intensities of light are easily tolerated. With the combination of more light and a larger field, much more becomes visible through the binocular microscope.

The conjunctiva is almost transparent, particularly in older persons, so that the blood vessels are easily seen. The red vessels are arranged in a thin layer against a contrasting white background. The walls of most of these vessels are so thin that they are barely discernible, whereas the blood cells circulating in them are visible. There is a conspicuous variation in many features of the circulation from vessel to vessel. In some there is a swift current, which flows evenly; in others the blood moves slowly and irregularly, and in still others the flow may even stop and be reversed in direction. In a few instances a pulsating movement synchronous with the heartbeat is observed. In some vessels there is a rushing and swirling of a turbulent stream. The aqueous veins, which were so named by Ascher because of their high aqueous content, are readily identified, and their course is easily traced. Delicate lymph channels can be identified in a few instances.

The modification of the slitlamp by which this examination is made possible is described. R. W. Danielson.

Haar, M. **Reiter's disease.** Acta Ophth., 1945, v. 23, pt. 2, pp. 143-150.

In rapid succession an 18-year-old boy developed conjunctivitis, bilateral iritis, prostatitis, and exudative polyarthritis. Gonorrhea was excluded, and the diagnosis of Reiter's disease was made. The eyes made a rapid recovery. The outstanding feature of the case was the pronounced exudation in the eye and joints.

Klar, R. **Corneal involvement in vernal conjunctivitis.** Klin. M. f. Augenh., v. 109, May-June, p. 385. (See Section 6, Cornea and sclera.)

Kove, Simon. **Stevens-Johnson syndrome (eruptive fever with stomatitis and conjunctivitis).** Am. J. M. Sc., 1945, v. 210, Nov., p. 611.

Two cases of Stevens-Johnson syndrome of unknown etiology and characterized by an eruptive fever with membranous stomatitis, purulent conjunctivitis, and severe constitutional reaction are reported. They were encountered within a 2½-week period with no history of contact with each other.

The first patient was treated with sulfadiazine orally in addition to local therapy and recovered completely. The other was desperately ill and was treated with both sulfadiazine and penicillin. After a protracted and extremely stormy course, the patient recovered completely except for a mild chronic residual conjunctivitis and bilateral synechiae.

The effect of either sulfonamide or penicillin therapy cannot be properly evaluated from a review of these two cases.

The etiologic agent may be related to the virus of mumps.

Theodore M. Shapira.

Nižetić, Z. **Swimming pool conjunctivitis or swimmers' (divers') conjunctivitis.** Klin. M. f. Augenh., 1943, v. 109, May-June, p. 320.

The term swimming pool conjunctivitis is misleading since it suggests that the infection is only acquired in closed artificial pools, which is not true. Epidemics have been observed in open bathing places such as the Black Sea and Lake Michigan. The author ob-

served six cases in the last two years. He proposes that it would be more appropriate to call the disease swimmers' or divers' conjunctivitis. F. Nelson.

Odegaard, Kristian. Purulent conjunctivitis with keratitis caused by *Neisseria intracellularis* (meningococcus). *Acta Ophth.*, 1944, v. 21, pt. 4, pp. 295-302.

A case of primary meningococcus kerato-conjunctivitis in a hospital maid is reported. Clinically the course resembled gonorrheal ophthalmia. Isolated meningococcus conjunctivitis is rare and some of the reported cases were complicated with meningitis. The diagnosis can only be made from a culture, and it is suggested that some of the cases diagnosed from smears as gonorrheal ophthalmia might have been meningococcus conjunctivitis.

Osterline, Gote. An investigation into the presence of lymphatic tissue in the human conjunctiva and its biological and clinical importance. *Acta Ophth.*, 1944, supplement 23, pp. 77.

The material for this study consisted of the conjunctivas of 92 persons varying in age from the newborn to 81 years. Most of them died within 24 to 48 hours following violent trauma. The conjunctiva was dissected from the tarsus and globe and stained in a solution of gallocyanine, which stains the follicles bluish black so that they can be counted under a binocular loupe. These counts and the histologic data show that the conjunctiva of the newborn is free from follicles. Follicles begin to form in early infancy and reach the maximum of 30 follicles in eyes about the age of eight years. At the age of 15 years their number begins to dwindle and at 25 to 35 years of age.

their average number is 10. After this age their number varies but little. Up to 15 years of age all subjects had follicles. As the subjects get older one encounters more and more without follicles. In childhood, the follicles are larger and more numerous in the upper conjunctival fold. With the age of the patient they become smaller and more evenly distributed. Microscopically the conjunctival nodules are similar in structure to lymphatic nodules elsewhere in the body. Biologically they are centers of reaction to external irritants. Their task is to participate in the defense of tissue against bacterial and toxic irritants. Correlating the number of follicles with the extent of conjunctival inflammation it appears that follicles are very rarely formed in a conjunctiva which is free from irritation; they were found in declining form in two out of 23 such membranes. Follicle formation is primarily associated with slight or subsiding inflammatory processes, too mild to produce marked clinical symptoms. There is no follicle formation in acute conjunctivitis. These findings indicate that folliculosis of the conjunctiva can not be differentiated into different types etiologically or morphologically, and that in all cases the follicles will eventually disappear spontaneously leaving no scars. (10 illustrations, 4 tables.)

Pavisc, Z. Early transplantation of mucous membrane from the mouth and conjunctiva in burns of the eye. *Ophthalmologica*, 1944, v. 108, Dec., pp. 297-304.

The author advocates early transplantation of mucous membrane in severe cases of cauterization and burns of the conjunctiva and cornea. When both eyes are affected he uses mucous

membrane from the mouth. When only one eye is damaged, conjunctival tissue from the upper fornix of the undamaged eye can be used if the burn is not too extensive. In several patients early transplantation only prevented a more marked symblepharon and did not prevent corneal leucoma, but in several others normal vision was preserved. The latter was especially true after acid burns. Max Hirschfelder.

Poulsen, A. G. **A case of melanocarcinoma conjunctivae.** Acta. Ophth., 1945, v. 23, pt. 2, pp. 151-160.

The literature is reviewed and a case reported in a 23-year-old woman. The growth recurred twice and microscopic examination after the third excision revealed the growth to be a melanocarcinoma. The clinical as well as the histological differential diagnosis between a benign and malignant naevus is difficult, and all conjunctival naevi should be considered as an intermediate stage between normal tissue and actual tumor tissue. Suggestive of transition into malignancy is the location at the temporal limbus, increased pigmentation and growth, vascularization from peripheral vessels, adhesion at the base, inflammatory symptoms, ciliary pain, recurrence after excision, and occasionally iritis. (Photomicrograph.)

Radnót, M. **Bacteriologic findings in gonorrheal conjunctivitis treated with sulfa drugs.** Klin. M. f. Augenh., 1943, v. 109, May-June, p. 344.

When sulfamid drugs are used in the treatment of ophthalmoblennorrhea, gonococci often disappear from the conjunctival sac in a few days. Occasionally gonococci can be found for a long time after clinical cure. Certain precautions are imperative to prevent recur-

rence and transmission of the disease by these carriers. Before discharge three smears taken at intervals of 48 hours should be negative. Gram staining should be used to avoid confusion with staphylococci which often resemble diplococci, although it is believed that some gonococci become Gram-positive during the administration of sulfa drugs. The final bacteriological examination should be carried out after the disappearance of clinical symptoms and after the patient is free from sulfa drugs. (References.)

Skydsgaard, Henning. **Polyarthritidis urethritica simplex with eye symptoms.** Acta Ophth., 1943, v. 21, pts. 1-2, pp. 107-118. (See Section 17, Systemic diseases and parasites.)

Sorsby, Arnold. **Ophthalmia neonatorum in England, 1844-1944.** Sight-saving Review, 1945, v. 15, Winter, pp. 187-196.

In 1844 more than 30 percent of all blind children lost their sight through ophthalmia neonatorum; in 1928 it was 28.5 percent and in 1944 not more than 9.2 percent. Three factors that brought about the decline are the Crede technique, compulsory notification of the disease, and the use of sulfonamides. The latter has been replaced by penicillin. A solution containing 2500 units per c.c. is recommended at half hour intervals although in the last seventy-two patients at White Oak hospital one drop of penicillin was instilled every minute. The formation of pus stopped in one half hour and the residual catarrhal conjunctivitis disappeared in two or three days. Ophthalmia neonatorum is not synonymous with gonococcal ophthalmia. Of 737 cases, 180 were caused by gonococcus, 271 by the vari-

ous types of staphylococcus, 119 cases by bacilli, and in 126 cases no organisms were found. Fifteen percent of all cases appeared to be caused by a virus.

I. E. Gaynon.

Ulrich, K. **Chemo-therapeutic treatment of gonorrhea.** *Klin. M. f. Augenh.*, 1943, v. 109, May-June, p. 347.

Thirteen infants with gonoblennorrhea neonatorum were given the sulfa drug orsulon. In 11 infants the eyes recovered completely in three to five days. One infant developed slight cyanosis. In another, a very feeble baby who could not tolerate the drug, the process was not influenced greatly. Recovery was slow and complications occurred in infants who were not breast-fed or were given only small amounts of mothers' milk. Only one of the 13 infants developed a corneal infiltration, which healed rapidly. Local treatment is unnecessary. (References.)

Vanýsek, J. **Conjunctivo-urethrosynovial syndrome of Fiessinger and Leroy or Reiter's disease.** *Časopis Lékařů Českých*, 1946, v. 85, March 15, pp. 343-347.

Several cases of conjunctivitis with arthritis and urethritis were observed during an outbreak of infectious keratitis. This disease, called Reiter's disease, usually follows an attack of diarrhea. Reiter claimed that he was successful in isolating a spirochete, which he called *Spirochete forans*, from the secretions. Fiessinger and Leroy, however, stated that the disease is a sequel of bacillary dysentery. The author observed seven patients with conjunctivitis and superficial punctate keratitis, in three of whom there was also iridocyclitis. Urethritis and arthritis were present in all patients. The illness

started after diarrhea. It lasted three weeks and longer. No gonococci and no spirochetes were found. While the bacteriologic diagnosis of bacillary dysentery was not established, the author believes that in the patients observed by him the syndrome was a complication of dysentery, which was prevalent at that time.

O. Felsenfeld.

Wain, Harry. **Ophthalmia Neonatorum—A historical résumé and present status in the United States.** *Sight-Saving Review*, 1945, v. 15, Winter, pp. 196-202.

The author discusses ophthalmia neonatorum from the point of view of gonorrhea. He describes the disease, its history in the United States, the Crede technique, and makes a plea for the eradication of the disease in the mother before the birth of the child. The incidence of blindness due to ophthalmia neonatorum has dropped from 30 to 2.4 percent.

CORNEA AND SCLERA

Becker, F. **The etiology and therapy of epidemic keratitis.** *Klin. M. f. Augenh.*, 1943, v. 109, May-June, p. 412.

In the treatment of epidemic keratitis (nummularis) the use of Greifswald dye solution and subsequent treatment with 0.5 to 1-percent salicylic acid solution and 10-percent zinc oxide ointment yielded very gratifying results. The same ointment was also administered successfully in a case of a severe post-traumatic herpes of the cornea.

Bedell, A. J. **Epidermoid carcinoma of the cornea.** *Amer. Jour. Ophth.*, 1946, v. 29, July, pp. 864-866. (5 figures.)

Chamberlain, W. P. and Boles, D. J. **Edema of cornea precipitated by quinacrine (atabrine).** Arch. of Ophth., 1946, v. 35, Feb. pp. 120-134.

Six cases of corneal edema following the use of quinacrine (atabrine) were observed in the Southwest Pacific area. Four of the patients are described in considerable detail. Each patient had been taking protective doses of quinacrine, from 0.1 gm. to 0.2 gm. of the drug, for several weeks before the onset of symptoms. Visual acuity was variable. There was diffuse haziness of the corneas due to evenly dispersed punctate, superficial opacities. Withdrawal of the drug resulted in gradual clearing of the opacities. Resumption of the use of the drug resulted in a reappearance of the edema. All four of the cases studied intensively showed some liver damage, and one of the patients died of hepatic necrosis.

John C. Long.

Friede, R. **The nature of congenital corneal degeneration.** Klin. M. f. Augenh., 1943, v. 109, May-June, p. 390.

Dystrophy of the cornea is a disease that is essentially congenital but becomes manifest during postnatal life.

Bückler described three readily distinguishable types. Friede observed a number of cases of congenital corneal dystrophy over a period of 20 years and investigated the heredity of the process of the various types. The type of heredity is recessive. In some patients remissions of more than 10 years duration occurred between the thirtieth and fiftieth year of life. The first opacities were always found near Bowman's membrane and the anterior layers of the stroma. The middle and posterior layers at the corneal periphery became involved later. Exceptions to this rule were rare. Most details concerning nu-

trition of the cornea are not yet known. The intake of nutrient material may take place through the limbus and its capillaries, through the posterior vitreous membrane and its endothelium and through the anterior vitreous membrane and its epithelium. Lesions of the anterior as well as the posterior barrier must lead to swelling and eventually to clouding of the corneal stroma. The water content in the stroma is kept constant though it is exposed to the aqueous barriers, but only if these structures are intact and their function is not impaired. The chemical structures in endothelium and epithelium on the one hand and in the stroma on the other are quite different. The epithelium forms an acid covering over the alkaline stroma. Bowman's membrane and its epithelium probably serve as filter. The functions of the vitreous membranes have not been investigated sufficiently but much may be surmised. In the congenital corneal dystrophies the most serious change takes place in the anterior vitreous membrane. A disturbance of filtration in that membrane occurs. The involvement of Bowman's membrane seems to be the primary process and that of Descemet's membrane the secondary. The other vitreous membranes of the eye never participate in the pathological process. It is probable that the disease is a local process rather than a general one. Friede is inclined to believe that all three types of congenital corneal dystrophy are caused by the same agent, namely a disturbance of the metabolism of Bowman's membrane and epithelium. The differences of clinical appearance and development of the various opacities may be caused by congenital differences in the structure of the stroma. The hyaline of which the

opacities in dystrophic corneas consist is probably caused by a chronic retention of certain substances which eventually leads to disintegration of the tissues and to permanent opacities in epithelium, vitreous membrane and stroma. (Bibliography.) F. Nelson.

Friedenwald, J. S., Hughes, W. F., Jr., and Herrmann, H. **Acid burns of the eye.** *Arch. of Ophth.*, 1946, v. 35, Feb., pp. 98-108.

The following acids, in buffered and non-buffered solutions, were tested on the rabbit cornea: hydrochloric, trichloroacetic, metaphosphoric, sulfosalicylic, picric, tungstic, and tannic. Clinical reactions produced by solutions of these acids on the rabbit cornea were studied over a pH range of 1 to 9.

Acid burns of the eye are essentially nonprogressive, and late relapses are uncommon. The severity of the lesion produced is directly related to the protein affinity of the anion. Anions with high protein affinity and protein-precipitating ability produce corneal lesions at a higher pH than anions with low protein affinity. Large anions with high protein-precipitating ability show poor penetration through the corneal epithelium and poor diffusibility in the stroma. It is suggested that the characteristics of acid burns of the cornea may be explained by the precipitation and denaturation of the proteins of the cornea. (7 photomicrographs.)

John C. Long.

Fieandt, Olaf. **A histologically examined case of corneal transplantation.** *Acta Ophth.*, 194, v. 22, pt. 1, pp. 36-43.

An eye with vision reduced to hand movements as a result of parenchymatous keratitis was treated by a corneal transplantation. The eye subsequently developed an anterior cham-

ber cyst, and was enucleated. The histologic picture of the transplanted cornea supports the claim of those who consider the transplanted cornea as a permanent transplant and not merely a scaffold for regenerative processes, as is claimed by Salzer and Löhlein. The transplanted area contained all the corneal layers. Bowman's membrane, present in the transplant, was partially absent in the surrounding cornea and completely absent at the margin of the transplant. Descemet's membrane was thinner in the transplant. The literature is reviewed. (5 illustrations.)

Ray K. Daily.

Gallenga, R. and Rossi, A. **Early relief of corneal affections with plesiotherapy (contact radiation).** *Rassegna Ital. d'Ottal.*, 1946, v. 15, no. 1 and 2, p. 7.

The authors report excellent results in ulcerous keratitis of various types, pannus, recent corneal opacities, and especially in herpetic keratitis. The optimum dose of radiation was 400 r, with a tension of 60 kVm and a 0.5 mm. copper filter. Working with 3 Ma at a focal distance of 6 cm., 100 r was administered per minute with the Gorla Siana instrument. The treatment is given daily for one week in acute inflammations, and the course is repeated in subacute and chronic conditions.

The best results were obtained in herpetic keratitis where corneal sensibility returned rapidly, proliferation of superficial vessels was checked, and congestion decreased.

Eugene M. Blake.

Grosz, Stefan. **A new remedy for the treatment of phlyctenular keratitis.** *Acta Ophth.*, 1944, v. 22, pt. 3, pp. 275-280.

The author found a 15-percent sodium irgamid (N-Dimethylacroyl-

Sulfamid) ointment to be non-irritating and well tolerated in phlyctenular conjunctivitis in children. It is particularly indicated in eyes which do not tolerate yellow oxide of mercury, and can be combined with the internal administration of iodine. Its action is attributed to vasoconstriction. Ray K. Daily.

Holt, M. and Cogan, D. G. **The cornea.** Arch. of Ophth., 1946, v. 35, March, pp. 292-298.

In connection with recent studies of the permeability and other properties of the excised cornea, Holt and Cogan thought that measurements of electrical impedance might be expected to give additional pertinent information. It is now generally accepted that the impedance of biologic tissues is directly related to their ionic permeability. In the same way that measurements of impedance of solutions of pure electrolytes may be considered to measure (aside from concentration effects) the ability of the ions to diffuse through the medium, measurements of impedance of the cornea may be considered to give a measure of the ability of the ions to move through this tissue.

The authors used the corneas of beef eyes and came to the following conclusions.

Electrical impedance of the excised cornea is considerable as long as the epithelium is present. The impedance of the stroma alone is slight. So far as impedance is an index of ionic permeability, this means that the epithelium offers considerable resistance to the passage of ions, whereas the stroma offers a resistance little more than that offered by an equivalent volume of isotonic solution of sodium chloride.

The corneal epithelium is an even

more effective semipermeable membrane than previous chemical measurements have shown it to be.

The impedance of the epithelium of the excised cornea is irreversibly decreased by bathing the cornea in a 25-percent solution of sodium chloride; it is unaffected by a 0.9-percent solutions of sodium chloride, calcium chloride, and sodium nitrate, and it is reversibly increased by a 10-percent solution of atropine sulfate, by a 4-percent solution of cocaine hydrochloride, and, especially, by solutions in which the cation is the potassium ion.

Jancke, G. **Cibazol treatment of keratoconjunctivitis nummularis epidemica and of other eye diseases.** Klin. M. f. Augenh., 1943, v. 109, May-June, p. 314.

Jancke reports most satisfactory results in the treatment of keratoconjunctivitis nummularis with 10-percent cibazol eye ointment twice daily. When the disease is severe it is necessary to give scopolamine regularly, and when extreme, one has to resort to intensive peroral administration of cibazol. Other infectious eye diseases such as corneal ulcers, dacryophlegmon, orbital phlegmon, and erysipelas respond well to intensive therapy. It can also be applied as an adjuvant in intraocular infections. It seems that trachoma can be cured by oral administration of cibazol alone. Combined with customary mechanical methods this is the shortest possible type of treatment of trachoma. (References.)

News items should reach the editor by the twelfth of the month

DEATHS

Dr. Benjamin George Dyer, Kalamazoo, Michigan, died May 15, 1946, aged 80 years.

Dr. Alan Fesch Knisely, Lima, Ohio, died June 12, 1946, aged 87 years.

Dr. John Alexander McCaw, Denver, Colorado, died March 28, 1946, aged 79 years.

Dr. Howard Wilber Peirce, Detroit, Michigan, died April 17, 1946, aged 65 years.

MISCELLANEOUS

Dr. Placidus J. Leinfelder, professor of ophthalmology, Iowa State University, was a member of the faculty committee which, after several months' study, recommended a two-year experimental plan for faculty compensation in the College of Medicine, Iowa City.

The plan, recently approved by the Iowa State Board of Education, adopts a salary schedule for the various professional ranks in medicine. Private clinical practice was authorized, with percentage limits based on individual salaries. Fees from private patients will be credited to the clinical department giving the service. From this income, the faculty doctors will be paid the additional stipulated percentage of their basic salaries. Funds remaining will be used for departmental equipment and scientific programs. Professors desiring to serve on a full-time basis will, as in the past, be permitted to do so.

Preliminary steps were put into effect immediately, according to the report published in the Iowa City Citizen of July 25th, and the plan will be in full force by July 1, 1947. After a two-year trial, the plan will be reviewed by the university authorities in consultation with the faculty of medicine.

The Army Institute of Pathology is in the process of undergoing a considerable expansion and change of organization. It will still continue to be the Institute of Pathology for the United States Army, but it will also function for the Veterans' Bureau and play an expanded role in the activities of the civilian profession.

On request of Major Gen. Norman T. Kirk, Surgeon General of the Army, the committee on pathology of the National Research Council, Division of Medical Sciences, late in 1945, prepared a report on the future development of the Institute. The report has been approved by the Surgeon General and by the War Department.

The essential recommendations in this report

are: (1) that a new building of adequate size be constructed; (2) that the Institute be organized in four divisions—Department of Pathology, Army Medical Illustration Service, Army Medical Museum, and American Registry of Pathology—each headed by a competent specialist; (3) that the staff of the Institute be drawn from both the commissioned ranks of the Army and from the civilian professions; (4) that a comprehensive educational and training program be undertaken; (5) that the vast store of material at the Institute be used for research; (6) that the services in pathology in the Veterans' hospitals be centralized at the Institute.

The American Registry of Pathology founded in 1922 thus is, and will continue to be, an integral part of the Army Institute of Pathology. There were, on January 1, 1946, over 43,000 cases registered. To effectuate the new plans as they relate to the Registry, the National Research Council, Division of Medical Sciences, appointed a committee on the American Registry of Pathology. The members of the committee are Howard T. Karsner, chairman, Cleveland; Col. J. E. Ash, Washington; Brig. Gen. R. Callender, Washington; Col. Baldwin Lucké, Philadelphia; Robert A. Moore, Saint Louis; Benjamin Rones, Washington; A. R. Shands, Jr., Wilmington; and Henry A. Swanson, Washington.

At the present time there are 14 registries as parts of the American Registry of Pathology. These include Registry of Ophthalmic Pathology, established in 1922, sponsored by the American Academy of Ophthalmology and Otolaryngology; Lymphatic Tumor Registry, established in 1925, sponsored by the American Association of Pathologists and Bacteriologists; Bladder Tumor Registry, established in 1927; Kidney Tumor Registry, established in 1940, and Prostatic Tumor Registry, established in 1943, sponsored by the American Urological Association; Registry of Dental and Oral Pathology, established in 1933, sponsored by the American Dental Association; Registry of Otolaryngological Pathology, established in 1935, sponsored by the American Academy of Ophthalmology and Otolaryngology; General Tumor Registry, established in 1937, sponsored by the American Society of Clinical Pathologists; Registry of Dermal Pathology, established in 1938, sponsored by the American Academy of Dermatology and Syphilology; Chest Tumor Registry,

established in 1942, sponsored by the American Society of Thoracic Surgeons; Registry of Neuropathology, established in 1943, sponsored by the American Association of Neuropathologists; Registry of Orthopedic Pathology, established in 1943, sponsored by the American Academy of Orthopedic Surgeons; Registry of Veterinary Pathology, established in 1944, sponsored by the American Veterinary Medical Association; and Registry of Gerontology, established in 1945, sponsored by the Gerontological Society, Inc.

Plans for additional registries are under consideration. A professional scientific society wishing to sponsor a registry should communicate with the Director, Army Institute of Pathology, 7th Street and Independence Avenue, S.W., Washington 25, D.C. The society appoints a committee to work with the Director in supervision of the activities of the Registry, and makes an annual contribution to the budget which is administered by the National Academy of Sciences.

All specimens in the Registry are available for review and research by competent investigators. Sets of slides and accompanying syllabuses on special fields are available for loan to the civilian professions and to officers in the Federal services. Physicians, dentists, and veterinarians are urged to send unusual specimens together with an abstract of the history to the Registry. The contributor receives a report on each specimen and is asked to keep the Registry informed of the follow-up on the patient.

Many diseases are so rare that any one individual or even the staff of any one hospital or clinic has a limited opportunity to study certain conditions and lesions. Conclusions in science must be based on not one, but many observations. Therefore, it is desirable to organize and support central agencies for the collection and filing of histories, specimens, and follow-up studies.

With the reorganization of the Army Institute of Pathology to be completed during 1946 and 1947, a full-time scientific director of the American Registry of Pathology will be appointed and sufficient clerks and technicians will be available to assure adequate use of the registries for diagnosis, research, training of young men, and education of the professions.

The American Registry of Pathology deserves support from the civilian professions in terms of contributions of materials by individuals and sponsorship of registries by societies.

The Ophthalmological Study Council is planning another course of lectures (this time with some laboratory work) to be given this winter, November 2nd to January 15th in St. Petersburg, Florida, by a very exceptional group of lecturers from all over the United States. Like the first course, this one will be devoted to the

basic subjects of Ophthalmology: Anatomy, Histology, Embryology, Heredity, Physiology, Biochemistry, Optics, Physiological optics, Pathology, Histopathology (including laboratory work with microscopes), Bacteriology, Refraction (theoretical and practical), Motility, Neuro-ophthalmology, Slitlamp (theoretical and practical in four sections), Surgical principles, Relations to general diseases, and Glaucoma (from all points of view). There will be over 360 hours of instruction. The fee is \$300.

Arrangements can be made to take special subjects either singly, or two or three at a time, when they are given simultaneously in alternating periods. For instance: Biochemistry by Kinsey, Optics by Lancaster, and Visual physiology by Linksz can be taken during 10 days. Glaucoma by Chandler and Medical ophthalmology by Wagener can be taken during one week. Motility by Burian and Refraction by Beach, Regan, and Lancaster can be taken during another 10 days. Pathology with microscopes, and laboratory work on Optics and on Physiology can be taken from December 21st through December 31st. Fees depend on the number of periods; the average is about \$40 per week.

First class hotel accommodations are from \$4 per day, single, to \$6 per day, double. Round trip rates by coach are very low. For example: Boston to St. Petersburg and return costs \$60.82 plus tax.

The 20th annual spring graduate course in ophthalmology and otolaryngology will be held at the Gill Memorial Eye, Ear, and Throat Hospital, Roanoke, Virginia, April 7 to 12, 1947.

SOCIETIES

The program for the Association of Military Surgeons, Eye, Ear, Nose and Throat panel discussion, October 11, 1946, at the English Room, Statler Hotel, Detroit, Michigan, follows:

Morning, 9 o'clock

Comdr. A. Duane Beam (MC), U.S.N.R., Detroit, Michigan. "Traumatic injuries of the eyes and their repair."

Lt. Col. James N. Greear (MC), A.U.S., Washington, D.C. "Rehabilitation of the blind."

Lt. Col. Gilbert C. Struble (MC), A.U.S., Valley Forge General Hospital, Phoenixville, Pennsylvania. "Repair of eye injuries" (Movie).

Lt. Col. E. L. Shiflett (MC), A.U.S., William Beaumont General Hospital, El Paso, Texas. "X-Ray reconstruction of orbit as an aid to surgical reconstruction."

Lt. Col. Ben. H. Senturia (MC), A.U.S., Saint Louis, Missouri. "Ear plugs for the prevention of deafness."

Lt. Col. Edmund P. Fowler (MC), A.U.S., New York, New York. "Irradiation of the eustachian tubes."

Afternoon, 2 o'clock

Lt. Col. Mercer G. Lynch (MC), A.U.S., New Orleans, Louisiana. "Laryngeal injuries and their repair."

Capt. Francis L. Lederer (MC), U.S.N.R., Chicago, Illinois. "Rehabilitation of the deaf in the Navy."

Lt. Col. Frank D. Lathrop (MC), A.U.S., Boston, Massachusetts. "Facial nerve repair due to war injury."

Dr. Julius Lempert, New York, New York (by invitation). "Lempert fenestra novovalis operation for the restoration of practical serviceable hearing in clinical otosclerosis" (motion picture of technique).

Honorary chairmen: Maj. Gen. Norman T. Kirk (MC), U.S.A., and Vice Adm. Ross T. McIntyre (MC), U.S.N.

PERSONALS

At the exhibit of the American Physicians Literary Guild held in San Francisco in conjunction with the A.M.A. convention, Dr. Joseph I. Pascal was awarded first prize for a humorous essay "If you must wear glasses—wear invisibles."

Dr. James C. Strong, recently released from Service, announces the opening of his office, 617 Majestic Building, Denver 2, Colorado.

Dr. Alston Callahan, professor of ophthalmology, Medical College of Alabama, announces the opening of his office, 908 South Twentieth Street, Birmingham, Alabama.

Dr. John C. Cunningham, 49 South Winooski Avenue, Burlington, Vermont, has been named chairman of the department of ophthalmology at the College of Medicine, University of Vermont, Burlington.

On November 21, 1946, Dr. Algernon B. Reese will deliver the deSchweinitz Lecture before the Section on Ophthalmology of the College of Physicians, Philadelphia.

Dr. Adalbert Fuchs of Vienna wishes to let his friends and colleagues in the United States know that he and Mrs. Fuchs have accepted employment with UNRRA and that, until further notice, his address will be: Headquarters, UNRRA, Shanghai, China.

ERRATA

The obituary of Dr. James Watson White which was published in the August issue of the Journal was prepared and written by Dr. Harold Whaley Brown, an associate of the late Dr. White.

CHEMICAL BURNS OF THE HUMAN CORNEA

RALPH S. McLAUGHLIN, M.D.
Charleston, West Virginia

A chemical burn of the cornea is defined as an injury which results from local contact with a chemical (solid, liquid, or vapor) to such a degree that there is alteration in the structure of the cornea and the conjunctiva. This alteration in structure is demonstrated by a positive stain when a 2-percent buffered solution of fluorescein is applied.

It has been the experience of the author to have practiced industrial ophthalmology in an industrial center where a large variety of chemicals is manufactured and utilized. These include particularly many of the newer solvents, plastics, alcohols, aldehydes, and hydrocarbons, as well as the intermediates involved in their manufacture. The observations discussed in this paper have been made through association with such establishments as Carbide and Carbon Chemicals Corporation, American Viscose Corporation, Westvaco Chlorine Products Corporation, Monsanto Chemicals, Ohio-Apex, and Belle Alkali Companies. The Carbide and Carbon Chemicals Corporation alone manufactures and ships over 200 different chemical compounds from their local operations, and it has been this firm which has sponsored and aided the present study. A companion paper¹ is presented on adjoining pages by the Chemical Hygiene Fellowship at the Mellon Institute, Pittsburgh, which is supported by that corporation. That communication presents a tabulation of

some 180 chemicals arranged according to the severity of injury they produce on the cornea of the albino rabbit, together with studies of burns of the rabbit cornea which have thrown light upon clinical observation.

The magnitude of the problem in one plant is shown by the data in Table 1. Each one of the patients in the cases listed was known to have had a chemical

TABLE 1
EXPERIENCE OF ONE PLANT WITH CHEMICAL EYE
IRRITATIONS AND BURNS, EXCLUSIVE OF
TRAUMATIC INJURY

Year	Dispensary Cases	Referred Cases
1942	663	85
1943	583	69
1944	926	82
1945	1,394	97
Totals	3,566	333

cal exposure which was at least severe enough to bring the employee to the dispensary, complaining of his eyes and requiring treatment. As can be seen, only 10 percent of the injuries were severe enough to be referred to the ophthalmologist, and, in this particular group, only one case was terminated with a loss of vision. In all of those treated in the dispensary, there was complete recovery. In a recent tabulation for 12 months in the same establishment, it was found that 52 percent of the chemical eye injuries were caused by vapors and mists,

31 percent by liquids, and 17 percent by solids. In due respect to the Safety Department of the corporation, it should be remembered that during a great portion of the period the plant was operating under wartime conditions with inexperienced, and in some cases inefficient, help, due to loss of regular employees to the Armed Services.

Every endeavor has been made to cooperate closely with plant Safety and Medical Departments in order to maintain an adequate program for the prevention and treatment of chemical burns of the eye.

FIRST-AID TREATMENT

Over the period of seven years covered by this study, it has been determined, beyond question of doubt, that early

following program has been accomplished, during this period, by Dr. Thomas W. Nale,³ medical director of the South Charleston Operation of the Carbide and Carbon Chemicals Corporation, and by me. The results obtained lead us to believe that the following technique is most desirable:

The immediate treatment of an eye burn is at the site of the accident. Specially built foot-operated eyewashing fountains are provided close at hand in every working area (fig. 1). The injured eye is washed thoroughly and at once with tap water, holding the lids open with the hands. No neutralizing substances are used, since study¹ of this practice reveals that not only do they do no good but that actually some are injurious in themselves. After the preliminary washing, the victim is at once transported to the medical dispensary, where equipment for first aid is held ready at all times.

A list of chemicals used in the plant is maintained in each dispensary. This list sets forth the severity of injury expected, and the acidity, alkalinity, or neutrality of any chemical in question. The more frequently used chemicals were evaluated on the basis of experiments made in rabbits' eyes.¹ A similar list is in the hands of the ophthalmic consultant, so that he may have some basis for judging in advance the therapeutic measures called for.

When a chemical eye burn is brought into the dispensary, the patient is placed in a reclining chair (Beck) and tilted back over a catch basin. The eye is inspected and then anesthetized with 0.5-percent pontocaine solution. Gross particles are removed with a moist cotton applicator. The eye is then irrigated with a continuous flow of normal saline, no pressure being exerted on the eye. Special equipment (figs. 2 and 3) consists

Fig. 1 (McLaughlin). Eye-washing fountain installed in a chemical unit. 1, Soft rubber eye piece; 2, foot peddle to control water flow.

treatment is of supreme importance to the ultimate outcome of a chemical burn of the eye.² Development of the

of a 5-gallon bottle mounted on a movable stand and equipped with a siphon (3-foot head). Irrigation is continued for 15 minutes, after which the eye is reexamined for gross particles and then stained with fluorescein. If the eye is damaged, the injured cells will take a typical fluorescent yellow-green stain. If a stain is observed, further anesthesia is produced with pontocaine, and washing proceeds for another 15 minutes. The stain is applied a second time and, if found to be positive, the case is considered to be an unequivocal chemical burn and is referred to the ophthalmologist. Time, here, is of importance, and it has been my experience that no more than two hours should elapse between the moment of the burn and the time when special treatment is rendered. Certainly, the prognosis grows worse as time passes, and a delay of six hours almost always results in some loss of vision.

It is possible to get moderately severe burns from vapors alone. In cases of vapor irritation, the same technique of emergency treatment is used as for other burns, except that it is not necessary to wash the eyes for as long, unless there is a demonstrable staining of the cornea. In all cases where washing is reduced to the first 15 minutes, a recheck of the eye is made with stain in two hours, and the patient is warned to report at once should any untoward symptoms develop in the suspected eye. This is done because a few chemicals have been observed to cause a delayed injury, producing a breakdown of corneal epithelium some hours after contact.

DENUDING, A SPECIALIZED TECHNIQUE

When I began the study of chemical burns of the eye, seven years ago, it was a debatable question whether or not some chemicals had a "delayed action." Such compounds frequently caused a loss

of vision due to opacification of the cornea and adhesions of the conjunctiva, following a symptom-free period of several hours after accidental contact. In searching for a scientific basis for this behavior, the most notable finding was the change in corneal structure produced by all alkaline and a few neutral organic compounds, but not by acidic compounds nor those neutral chemicals which experience shows to be relatively harmless.

The corneal structure is best observed with the high power of the biomicroscope under retroillumination,⁴ with occasional resort to direct illumination. The change consists in the presence of areas of opacity in the superficial layers of the corneal epithelium. They vary in size, possess a grayish tint, and have well-defined margins. They suggest keratitic deposits, but direct illumination reveals them to lie immediately posterior to the precorneal film⁵ in the most superficial epithelial layers anterior to Bowman's membrane. The opaque areas are seen to be stained a faint green by fluorescein when observed by direct illumination.

We at first thought that the offending chemical had penetrated into the epithelial cells, there reacting with the cytoplasmic protein. However, this would bind the chemical in place and probably neutralize its ability to injure other cells. Studies reported by Carpenter and Smyth¹ make it appear more probable that the foreign compound initially is physically adsorbed upon protein structures of the corneal epithelium. Following this, a portion of the adsorbed chemical denatures cellular protein, resulting in necrosis. The remainder is liberated slowly with its chemical nature unchanged, to diffuse from the original site of adsorption into previously unaffected tissue. Therefore, instead of a delayed effect, there is a progressive action which may spread to involve the entire depth of the epithelium

Fig. 2 (McLaughlin). Equipment utilized in irrigating chemical burns to the eye.

and, eventually, Bowman's membrane, at which point irreparable damage to the tissue results.

The greater number of chemicals behaving in this way are alkaline, and at first it appeared that neutralization of the compound bound to corneal epithelium would halt the progressive action. However, animal experiment¹ demonstrated no amelioration of injury from attempted neutralization. It was then apparent that only one form of treatment was possible, that of mechanical removal of the involved cells before a progressive action could be initiated. This operation is named "denuding." As carried out by me, the manipulation differs in purpose and thoroughness of control from débridement.

No evidence for a progressive action of acids has been observed. They apparently react rapidly with cell proteins, coagulating them, and themselves being

neutralized in the process. The extent of an acid burn of the cornea is, of course, determined by the amount and concentration of acid in the eye and the length of time that elapses before it is washed out. The method generally used in treating an acid burn is to débride the dead tissue and treat the eye symptomatically. Following the appearance of the communication by Mann⁶ on corneal healing, the author employed clinically the methods described and concluded, in conflict with her findings, that the course of healing is not prolonged by removing destroyed tissue. Furthermore, its removal reduces secondary infection by eliminating the substrate for bacterial growth. Consequently, I still consider débridement essential following corneal burns caused by acids.

The denuding technique in its early application consisted of complete removal of the epithelium down to Bowman's

membrane. The biomicroscopic picture of the completely denuded Bowman's membrane is that of a smooth surface, without evident cellular structure, having regularly placed, minute dimples which are the rami perforantes⁷ of the corneal nerves. Although we have later shown that such radical removal of tissue is unnecessary, we do know that the epithelium is rapidly replaced, and we have seen indication that the two methods of regeneration described by Mann⁶ are correct.

Denuding, as used today, removes only such part of the tissue as is involved, and the manipulation is controlled by repeated examination with the biomicroscope. The instrument of choice is a round tooth pick wound with cotton in the nature of a swab. The epithelium is softened with 4-percent cocaine-hydrochloride solution, which also acts as a local anesthetic. The applicator is started in the center of the involved area with just enough pressure to distort slightly the corneal surface. With a circular motion, the applicator is carried progressively from the center to the outside of the area, where it is lifted. This action is repeated over the entire affected area until the biomicroscope reveals no more of the clouded cells, but only a rough surface indicative of ruptured cell bodies and fragments of cells. After the corneal denuding is completed, a careful denuding of the conjunctiva is performed. Here the applicator is passed from the limbus to the cul-de-sacs, each lid swept from side to side, and the cul-de-sacs finally swept. The eye is then flushed with stainless solution of merthiolate, which acts not only to remove the denuding refuse, but also as an antiseptic.

Study of the eye during the denuding process may be confusing, for the pre-corneal film has been removed and allowance must be made for its absence. In

the final check on the biomicroscope, the meniscus of the lacrimal fluid where it meets the lower lid should be observed carefully, and no cellular debris should be left. Each eye is routinely closed with 5-percent sulfathiazole ointment (sulfa-

Fig. 3 (McLaughlin). Demonstrating method of continuous irrigation of chemical burns to the cornea.

diazene is equally efficacious) and a lid-immobilizing patch is applied.

During the first consultation, special attention should be given to all possible foci of infection, especially the teeth. While treatment of the foci need not be started at this time, it is important that they be noted on the record. Treatment is started if the eye does not heal by first intention. It has been the author's observation that more vision has been lost in chemical burns due to focal infection than by the actual effect of the offending agent.

AFTERCARE OF THE DENUDED EYE

This subject is of utmost importance

and careful attention to detail will be rewarded with satisfactory results. Warning is given the patient at the first consultation that considerable pain is to be expected, due to the denuding, and each patient is provided with 0.5-percent ophthalmic pontocaine ointment, with instructions to apply it aseptically to the eye as frequently as is needed to control pain. Some persons, due to a difference in pain threshold, will require barbiturates, and a few may need morphine. The immobilizing patch is to be worn at all times except during actual treatment.

The eyes are inspected under fluorescein stain upon the day following denudation and, if found to be healing by first intention, no change is made in therapy. If, however, undue reaction is found, the eye is placed at temporary rest by the instillation of a few drops of 5-percent homatropine solution, and 5-percent sulfathiazole ointment is added at four-hour intervals. The choice of homatropine is made so that loss of time, an important factor in industrial practice, will be minimized if the eye heals promptly.

On the third day, inspection is again made, and, if healing is not complete, there is presumptive evidence that the burn has converted to an infected ulcer, and active combative treatment is instituted. The eye itself is sprinkled with methylene-blue powder, and the excess flushed away. Pontocaine, sulfathiazole, and the immobilizing patch are continued. An intramuscular injection of 5 c.c. of proteolac (G. D. Searle and Company) is given, and administration of maximum doses of sodium salicylate is started. Dental X-ray or medical examination of other foci is made, and such areas, if amenable to treatment, are removed at the earliest possible moment, regardless of the condition of the eye. In the event that surgical treatment of foci is to be undertaken, the patient is hospitalized and intravenous

typhoid-vaccine fever therapy is begun. The surgical procedures are so arranged that they fall on the rest day in the typhoid series. At this point, the eye is atropinized because prevention of time loss is no longer a factor to be considered, and the whole attention must be turned toward the healing of the eye.

After healing has taken place and the cornea has been free from fluorescein staining areas for 48 hours, any residual opacity is treated with increasing percentages of dionin or with choline chloride.

CASE REPORTS

Table 2 lists 500 consecutive cases of chemical eye burn treated by the author in the last three years. Details of the seven cases in which some loss of vision resulted follow this table.

Due to the fact that they were in the process of manufacture, the chemicals listed varied in concentration and purity. Many of them are recorded by the abbreviated names under which they are known in industry, and many are actually combinations of several substances which are used in the manufacture of a given product. While the author realizes that inaccuracies exist, it is, nevertheless, significant that the denuding technique is efficacious upon burns from a wide variety of chemicals.

CASES OF LOSS OF VISION

Case 1. Acetic-anhydride burn. This case was treated with the proper technique but the patient had several abscessed teeth and was very uncoöperative, refusing to remain in the hospital. The teeth were finally extracted on the second admission to the hospital but irreparable damage to the eye had taken place. Total loss of vision of the injured eye resulted. Notable in this case is the fact that another employee was injured as severely in the same accident. He was

given identical treatment, and healing was by first intention.

Case 2. Fifty-percent sodium-hydroxide burn. This case was not seen by

the author for 48 hours after the burn. On first examination, it was determined that Bowman's membrane was involved, and a poor prognosis was given at that

time. The final vision in this case was 20/50.

Case 3. Lime burn. The patient in this case was treated by a general practitioner for three days previous to the time he was seen by the author. At that time, damage had already resulted. The patient was in poor health, having several infected teeth. After a protracted convalescence, the final vision in the injured eye was 20/60.

Case 4. Lime burn. This case was first seen by the author four days after the injury and no treatment of any kind had been given the patient. General health was poor, and loss of vision in the injured eye was total.

Case 5. Lime burn. The patient was given no first aid but was seen by the author within three hours after the injury. Healing was by first intention, but the newly formed epithelium broke down on the seventh day. Several abscessed teeth were removed on the same day, but a residual scar resulted. Final vision in the injured eye was 20/25.

Case 6. Fifty-percent sodium-hydroxide burn. The patient was not given the usual first-aid therapy and was not seen by the author until 24 hours after the injury. His general health was good. Final vision in the injured eye was 20/25.

Case 7. Twenty-five percent sodium-hydroxide burn. This case was treated according to the routine, but the patient

had many broken and abscessed teeth and was in poor health. The final vision in the injured eye was 20/30.

SUMMARY

From the study of 500 consecutive cases, the following conclusions are drawn:

1. Immediate first aid, followed by long flushing with water is of the utmost importance. No attempt at neutralization is recommended.

2. Specialized treatment by an ophthalmologist should be given within two hours after the injury. Further delay threatens recovery of full vision.

3. Denudation is the treatment of choice.

4. It is noted that the majority of cases, 456, or 91.2 percent, healed in 48 hours with no loss of vision; 37, or 7.4 percent, healed slowly, but without loss of vision; 7 cases, or 1.4 percent, healed with a residual loss of vision. The loss of vision in all seven cases was the result of inadequate preliminary care or health conditions present before the eyes were burned.

5. There is no mention made of conjunctival adhesions in this discussion, and it is notable that with the technique described the author had no such complication in any of these 500 consecutive cases.

CHEMICAL BURNS OF THE RABBIT CORNEA*

CHARLES P. CARPENTER, PH.D., AND HENRY F. SMYTH, JR., PH.D.
Pittsburgh, Pennsylvania

One of the most frequent and disturbing injuries that may occur in the manufacture of chemicals is accidental introduction into the eye. If time lost as a result of the accident is to be minimized, and impairment or loss of vision prevented, coördinated effort on the part of the plant medical service, the ophthalmologist, and the laboratory investigating plant hazards is essential. The clinical phases of this effort are discussed by McLaughlin¹ upon adjoining pages of this Journal. Where the behavior of the offending agent introduced into the eye has been determined by experiment upon animals, a better estimate of the potential seriousness of the injury may be made, and a more rational therapy instituted.

ESTIMATION OF EYE HAZARD BY THE RANGE-FINDING TEST

We have described elsewhere a quantitative method of assay to delineate the ability of a material to cause chemical burns of the rabbit eye as part of our range-finding test.² Because of the frequency of accidental entry of fluids into the eye, it was thought worthwhile to grade the severity of eye burns resulting from a large number of chemicals and mixtures. The work was started in 1938, and more than 4,000 rabbit eyes have been used to obtain this information.

We standardized the test for our own use six years before the communication of Friedenwald, Hughes, and Hermann³ was published, but it has been possible to employ a scheme not unlike theirs to translate each injury into a numerical score. The system is shown in table 1.

* From the Mellon Institute.

The validity of this procedure is established by the fact that, in those eyes in which we have followed healing, the time required for repair and the area of any terminal corneal scar were roughly proportional to the numerical score assigned to the initial injury. Moreover, the scores for injuries caused by decreasing volumes or decreasing concentrations of a chemi-

cal form a smoothly descending numerical series.

The individual numerical scores of each eye treated with a given volume or concentration of a chemical are added together and then divided by the number of eyes (usually 5) to obtain the score of the injury caused by the treatment. We

have selected a level of 5.0 as representative of severe injury. This figure corresponds to necrosis, visible only after staining and covering about three fourths of the surface of the cornea; or a more severe necrosis covering a smaller area.

When a test is to be performed, normal albino rabbit eyes are selected on the basis of absence of grossly visible staining by a 5-percent aqueous solution of fluorescein sodium, flushed with distilled water 20 seconds after application. After a two-hour interval to allow the eye to return to normal, 0.005 ml. of the undiluted material is applied to the center of the cornea while the lids are retracted. About one minute later, the lids are released. This procedure is necessary to prevent the removal of a portion of the dose by the very efficient wiping system of the lids before intimate contact has been made with the eye. Eighteen to 24 hours later, the eye is examined in strong diffuse daylight, then stained with fluorescein, and the injury scored. Guided by the result and the table of injury grades below, additional applications are made until the chemical can be assigned to one of the grades we recognize. If large volumes are applied, the lids are held closed for one minute before the animal is released.

Where dilution of a chemical is necessary, our preferred solvent is propylene glycol from a batch shown to cause no injury. Preference is next given to water, and in some cases a deodorized kerosene known as "Deobase" has been used.

Our grading system is set forth in table 2. No ambiguities have yet been found, although they might be expected in a system that depends partly on volume and partly on concentration. The combination is necessary to separate the damage produced by chemicals of obviously

TABLE 2
GRADES OF INJURY EMPLOYED FOR RATING THE
RELATIVE DAMAGE PRODUCED BY
CHEMICALS IN THE EYE

Injury Grade	Definition
1.	0.5 ml. undiluted gives injury of 0 to 1.0 points
2.	0.5 ml. undiluted gives injury of over 1.0 up to 5.0 points
3.	0.1 ml. undiluted gives injury of up to 5.0 points (0.5 ml. gives over 5.0)
4.	0.02 ml. undiluted gives injury of up to 5.0 points (0.1 ml. gives over 5.0)
5.	0.005 ml. undiluted gives injury of up to 5.0 points (0.02 ml. gives over 5.0)
6.	Excess of 40% solution gives injury of up to 5.0 points (0.005 ml. gives over 5.0)
7.	Excess of 15% solution gives injury of up to 5.0 points (40% gives over 5.0)
8.	Excess of 5% solution gives injury of up to 5.0 points (15% gives over 5.0)
9.	Excess of 1% solution gives injury of up to 5.0 points (5% gives over 5.0)
10.	Excess of 1% solution gives injury of over 5.0 points

diverse abilities to injure that cannot be distinguished on the basis of the reaction to 0.005 ml. undiluted.

A total of 180 chemicals arranged according to the injury grades in which they fall appears in table 3. It must be recognized that in many cases somewhat impure industrial products have been tested, and impurities may possibly place some compounds in a grade other than that which would be occupied by a pure preparation. An asterisk (*) marks chemicals known to have caused loss of vision or very slowly healing corneal burns in industrial use, exclusive of injury produced only by vapors, which is a quite separate problem. It will be seen that the asterisks are associated with the higher grades. It must be recognized that a viscous chemical is less likely to reach the eye than is a more mobile compound and, accordingly, the grades here defined do not reveal the true hazard of handling the compounds, but rather their relative potential ability to cause damage once they reach the eye.

As related by McLaughlin,¹ the lists have been used with profit by one industrial medical service for prediction of the probability of permanent injury in a particular accident and for indication

in the plant dispensary of the therapeutic measures that are to be followed. Although these lists have been found useful and fairly reliable in practice, there have been a few instances in which they have

TABLE 3

INJURY GRADES OF SOME CHEMICALS WHEN APPLIED TO THE RABBIT EYE

Grade 1 (0.5 ml. undiluted yields score of 0 to 1.0)

Butyl phthalyl butyl glycolate	Ethylene glycol diacetate
1-3 Butylene glycol	Glycerine
"Carbowax" compound 1,500	Hexaethylene glycol
"Carbowax" compound 4,000	Methyl acetyl ricinoleate
Castor oil	Methyl "Carbitol" formal
Deobase (deodorized kerosene)	Methyl "Cellosolve" acetyl ricinoleate
Diallyl phthalate	Methyl phthalyl ethyl glycolate
Dibutyl "Cellosolve" phthalate	Methyl styryl phenyl ketone
Di-2-chlorethyl formal	Nonaethylene glycol
Dicyanoethyl sulfide	Polyethylene glycols 200, 300, 400, 600
Di-2-ethylhexyl phthalate	Polypropylene glycol
Diethylene glycol	Propylene glycol
Di-isobutyl ketone	Tetradecanol
Dimethoxy tetraglycol	Tetraethylene glycol
Dimethyl tetrahydrophthalate	Tri-2-ethylhexyl phosphate
Dipropylene glycol	Triethylene glycol
Ethoxy triglycol	Tri-isopropyl phenyl phosphate
2-Ethylhexyl acetate	
Ethylene glycol	

Grade 2 (0.5 ml. undiluted yields score of over 1.0 and not over 5.0)

Allyl chloride	Isopropenyl acetate
Butyl "Carbitol" acetate	Methyl borate (96% ester)
"Carbitol"	Methyl "Carbitol"
"Carbitol" acetate	Methyl "Cellosolve" acetate
Chlorethyl benzene	Paraffin oil U.S.P.
Dibutyl "Cellosolve" succinate	Propylene glycol diacetate
Diethylene glycol diacetate	Pyruvic aldehyde
Dimethyl "Carbate"	Thiodiethylene glycol
Dimethyl phthalate	Tributyl phosphite
2-Ethylhexyl-2-ethylhexanoate	
Ethylene cyanohydrin	

Grade 3 (0.5 ml. undiluted yields score of over 5.0 and 0.1 ml. yields not over 5.0)

"Cellosolve"	Ethylene dichloride
"Cellosolve" acetate	Hydroxyethyl acetamide
Diallyl maleate	Methanol
Dicyanoethyl amine	Undecanol
Diethyl "Carbitol"	Tributyl phosphate
Dimethyl maleate	Oil of citronella
Ethanol	Methyl salicylate
Ethyl benzene	Methyl benzyl "Cellosolve"
Ethyl propyl acrolein	Methyl "Cellosolve"

Grade 4 (0.1 ml. yields score of over 5.0 and 0.02 ml. yields not over 5.0)

Acetonyl acetone	Formamide
Butyl "Cellosolve"	Isophorone
3-Chloropropane diol-1,2	Isopropanol
Dichlorethyl ether	Methyl acrylate
Diethyl "Cellosolve"	Methyl "Carbitol" acetate
Dioxane	Methyl ether of propylene glycol
Epichlorhydrin	Propylene oxide tetramer
Ethyl acetoacetate	*Styrene
Ethyl ether of propylene glycol	Tetrahydrodimethyl furane
Ethylene glycol monacetate	Triethylene glycol dichloride
Ethylene sulfide	Trimethyl cyclohexanone

Grade 5 (0.02 ml. yields score of over 5.0 and 0.005 ml. yields not over 5.0)

Acetol	2-Ethyl hexoic acid
Acetone	Ethyl mandelate
*Allyl alcohol	Ethylene glycol diformate
Butyl "Carbitol"	Glyoxal (32.8% technical)
Cyclohexanone	Hydroxyethylene diamine
Diacetone alcohol	Isobutanol
2,3-dichloropropanol-1	Isopropyl mandelate
Diethanolamine	Isopropyl oil
Diethyl sulfate	Mesityl oxide
Diethylene triamine	Methyl diacetoacetate
Diglycol chlorhydrin	Methyl-3-hydroxybutyrate
Dimethyl dioxane	n-Morpholine ethanol
Dimethyl furane	Methyl dioxolane
Diethyl tetrahydrophthalate	Pentane dione
Ethyl borate	Phenyl ethanolamine
Ethyl crotonate	Propylene oxide
Ethyl hexane diol	Soap, USP tincture green
2-Ethyl hexanoic anhydride	Triethanolamine
2-Ethyl hexanol	Tetraethanol ammonium hydroxide (40%)

Grade 6 (0.005 ml. yields score of over 5.0, excess of 40% solution not over 5.0)

Dibutoxy tetraglycol
2-Ethylhexyl acrylate
Tri-isopropanolamine

Grade 7 (0.005 ml. and 40% solution yield scores of over 5.0, 15% solution not over 5.0)

n-Butanol	Mercaptoethanol
Benzyl "Cellosolve"	Methyl acetoacetate
Cyclohexanol	Morpholine
*Ethylene chlorhydrin	Phenyl methyl carbinol
*Ethylene imine	Propylene chlorhydrin
Glycolic acid	Toluene
Isopropanolamines, mixed	

Grade 8 (0.005 ml. and 15% solution yield scores of over 5.0, 5% solution not over 5.0)

Caproic acid	Phenyl methyl ketone
*Di-2-ethylhexyl amine	Soap (granulated white)
Di-n-Hexyl amine	Succinic acid
*Dimethyl sulfate	Succinic anhydride
*Ethylene diamine	Tetramethyl ethylene diamine
*Formaldehyde	Trimethyl adipic acid
Lactic acid	

Grade 9 (0.005 ml. and 5% solution yield scores of over 5.0, 1% solution not over 5.0)

*Acetic anhydride	Piperazine
*Ammonium hydroxide	*Propylene imine
*Ethyl chloracetate	*Sulfuric acid
2-Heptadecyl imidazoline	Tributyl phosphine oxide
Menthol	Trimethyl cyclohexanol
*Methyl silicate	3,5-Xylenol
Monoethanolamine	

Grade 10 (1% solution yields score of over 5.0)

*Maleic anhydride
*Sodium hydroxide

* Compounds known to have caused severe human eye injury.

resulted in misleading prognoses regarding particular eye burns. These difficulties can be attributed largely to the fact that workmen are unable to inform the plant dispensary fully about the composition of fluids which they handle. There is also

uncertainty of the relative sensitivity of human and rabbit eyes.

In general, only materials are included whose chemical names can be given. It is of some interest to relate that three commercial shampoos have been found

to fall in grades 4 and 5, and that those synthetic detergents which were tested fall in grades 5 to 8.

NEUTRALIZATION OF ALKALI AND ACID BURNS

Although it might be expected that acid or alkali burns of the eye could be treated effectively by immediate neutralization, such has not proved to be the case with experimental burns of rabbit eyes. Both eyes of a rabbit were burned with acetic anhydride and flushed with water. One eye was then treated with milk of magnesia while the other served as a control. Repeated trials revealed no reduction in healing time nor any appreciable decrease in the severity of the burns. Actually, in some cases the injury was aggravated. This finding led to an investigation of the reaction produced by milk of magnesia on the normal rabbit eye. Four popular brands of the preparation were procured and 0.5-ml. amounts were instilled morning and afternoon daily. The eyes were stained each day with 5-percent fluorescein sodium, which by test had been found to cause no damage in itself upon repeated application. On the third or fourth day of treatment, necrosis involving 40 percent or more of the cornea resulted from instillation of two of four samples. This effect persisted while the daily administration of milk of magnesia continued. It required three to four days for the eyes to attain a normal condition after cessation of the doses. This irritative action was produced mechanically, it is believed, by brucite, a crystalline form of magnesium hydroxide, which appears in the amorphous product after storage.

The use of 2-percent citric acid as a flushing agent in the treatment of alkali burns of the eye has been proposed by Ridley.⁴ To investigate the efficacy of

this treatment, corneal burns were produced on both eyes of an anesthetized rabbit with 0.2 ml. of 0.5-percent sodium hydroxide, and the eyes were irrigated with 2-percent citric acid and 0.85-percent saline, respectively, for a 30-minute interval. At the end of this period, the anterior portion of the conjunctiva of the eye washed with citric acid had a coagulated appearance with extreme congestion and edema elsewhere. With slit-lamp observation, the lens was barely visible through the corneal opacity. The saline-treated eye had a congested conjunctiva, and the corneal opacity was about one half as dense as that of the other eye. Both eyes revealed complete surface necrosis upon staining with fluorescein the following day. The eye washed with citric acid showed opacity of the endothelium and Descemet's membrane with a cloudy stroma, whereas those structures were less injured than was the epithelium in the saline-treated eye. On the fifth day, the eye washed with citric acid had a thickened cornea, feathery opacity of the epithelium and stroma, and opacity of the endothelium. Macroscopically the opacity was very pronounced, and fluorescein stained the surface completely. At this time, the saline-washed eye was normal, with no opacity nor surface necrosis. After 17 days, the citric-acid-treated cornea contained a 3- by 3-mm. area filled with fluid in which were seen many punctate bodies, in all probability a leucocytic infiltration. There was considerable vascularization of the paralimbal region, and diffuse fluorescein staining of the cornea. After one month, this eye bore no resemblance to a functional organ because of necrosis, fibrosis, and conjunctival evagination.

To evaluate the effect of irrigation with 2-percent and 0.5-percent citric acid alone, normal unburned eyes of rabbits

under anesthesia were used. After 30 minutes, the left eye which received 2-percent citric acid had a cloudy cornea and edematous lids. The right eye, washed with 0.5-percent acid, had the same type of injury to a lesser degree. The opacity was localized in the internal layers of the cornea, either deep in the stroma or in Descemet's membrane and the endothelium. Twenty-four hours after the irrigation the left eye showed solid opacity and 100-percent necrosis with fluorescein. The right eye was cloudy and 80 percent of the cornea stained. After two weeks, the left eye was opaque, with a thickened cornea. The surface had 10-percent dense necrosis surrounded by opacity over the pupillary area, with some vascularization from the dorsal limbus. The stroma of the right eye was clearing nicely, but opacity of deeper layers was still visible under slitlamp observation. After the lapse of almost a month, there was a 5-mm. staphyloma over the pupillary area, which ruptured while the rabbit eye was being examined. The right eye showed cloudiness throughout the cornea under the slitlamp, an opacity that was also visible without aid.

Obviously, even though a single instillation of 0.5 ml. of 2-percent citric acid produced corneal necrosis in only one of five rabbit eyes, and applications repeated for seven days produced only sporadic nonpersisting small areas of necrosis, the 2-percent solution is absolutely and unequivocally to be avoided for prolonged irrigation. The same is true for 0.5-percent citric acid as an irrigating agent.

QUALITATIVE STUDIES ON ALKALI BURNS

The remarkable healing of alkali burns of the human eye which had been treated by simple denudation-led McLaughlin¹ to inquire into the mechanism of action underlying the necessity for complete re-

moval of the affected tissue as a means of preventing penetration and subsequent damage to the eye. A request for collaboration in the investigation of these problems was made to us.

The first matter for consideration was the suitability of the eye of the albino rabbit for test purposes. Walls⁵ states that a Bowman's membrane is seldom discriminable in the placentalian eye and in lower animals cannot ordinarily be discerned as a distinct part of the substantia propria. Our inability to measure the thickness of Bowman's membrane in the living animal by means of the slitlamp led us to the examination of stained histologic preparations, as differences in structural dimensions between the human and rabbit cornea might well have an important bearing on their respective responses to treatment after chemical burns.

Stained histologic sections of normal human and rabbit corneas were measured microscopically. The human corneal epithelium and Bowman's membrane measure 45.4 and 8.4 microns, respectively, compared to 33.6 and 1.75 microns for the corresponding structures in the rabbit eye. Although these figures do not represent *in vivo* dimensions, they illustrate the relative differences. The greater thickness of the epithelium of the human cornea presents a better mechanical barrier to chemicals penetrating to Bowman's membrane. Furthermore, this thicker epithelium of the human eye will permit deeper denudation for the removal of the offending agent without damage to the underlying Bowman's membrane, the integrity of which must be preserved if scar formation is to be prevented. This quantitative difference in structure may offer a decided advantage to the ophthalmologist in treating human-eye burns by the denudation technique. (The foregoing refers to a structure discriminable in

stained preparations, which we interpret as Bowman's membrane.)

Eye injuries produced by chemicals may be divided into three categories; namely, those produced by neutral, acid, and alkaline materials. Acid causes an immediate reaction which does not appear to increase in depth with time. Neutral chemicals usually act similarly, but some cause delayed burns. For example, the history in a few human cases which we observed could be explained only on the basis of a delay of several hours between contact with a fluid ester (methyl silicate) and development of injury. The mechanism causing a delay is not yet clarified. Acid and neutral burns were not investigated in the present study. Following alkali burns, McLaughlin¹ found, clinically, that immediate denudation of the involved area becomes necessary to prompt healing, presumably because it prevents penetration of alkali into Bowman's membrane. This fact raises the question as to what may happen after alkali reaches the eye. The damage may be caused by the lytic action of the alkali *per se*, by a product formed as a result of its chemical union with protein, or possibly by the elaboration of some agent from injured cells which stimulates the inflammatory process.⁶

The presence of alkali retained after flushing was demonstrated by the use of an ordinary pH indicator. Rabbits were anesthetized, and 0.05- to 1.0-ml. amounts of aqueous 4-percent sodium hydroxide were pipetted onto the cornea and allowed to remain for 30 seconds. Irrigation or continuous surface flushing of the eye with 0.85-percent sodium chloride was then instituted and continued for 30 minutes. Retention of hydroxyl ions was determined by excising a 2- or 3-mm. circle of corneal epithelium and testing its reaction. The tissue was at once mounted in a sealed hanging-drop prep-

aration in unbuffered 0.03-percent metacresol-purple indicator adjusted to the midpoint of its range, which covers pH 7.6 to 9.2. This indicator was selected because its range is above pH 7.2, the reaction of the normal surface of the rabbit cornea. Similar pieces of corneal tissue were always taken from the unburned eye of the same rabbit to serve as controls. Numerous trials with such preparations demonstrated that normal corneal epithelium was acid to the indicator, as it produced a yellow color, whereas tissue from the alkali-burned eye was strongly basic as evidenced by the development of a purple color. Furthermore, when a series of rabbits were treated and killed singly at various intervals of time, traces of alkali could be demonstrated, colorimetrically, 24 hours following the application and flushing.

The pH of the normal and alkali-burned corneas was also determined electrometrically with a glass electrode shaped to fit the curvature of the eyeball. Eyes were burned with 0.2 ml. of 1.0-percent sodium hydroxide and also with the same amount of a 5-percent aqueous solution of a less highly ionized alkali, ethylene diamine. All burned eyes were irrigated with physiologic saline for 30 minutes before the surface pH was determined. The left eye of each rabbit was burned, and the right eye served as a control.

The figures given in table 4 are in-

TABLE 4
ELECTROMETRIC pH DETERMINATIONS OF BURNED
AND NORMAL RABBIT EYES, AFTER
30-MINUTES' FLUSHING

	NaOH	Ethylene Diamine
Surface pH of burned left eye	8.0	8.1
Surface pH of normal right eye	7.2	7.2
Aqueous humor of burned left eye	8.5	8.7
Aqueous humor of normal right eye	8.2	8.2

teresting in that the normal pH of aqueous humor of the human eye according to Best and Taylor⁷ is 7.1 to 7.3, whereas the determinations on normal rabbit aqueous humor indicate a pH of 8.2, or 10 times the hydroxyl-ion concentration of the human aqueous. The demonstration of increased alkalinity of the aqueous humor following sodium-hydroxide and ethylene-diamine burns illustrates the ability of alkaline materials to penetrate the rabbit cornea. It would be expected, therefore, that where the buffering capacity of the aqueous humor is exceeded, damage to delicate internal structures of the eye will occur.

An *in vivo* test was devised to verify further the presence of alkali in tissue burned with sodium hydroxide. This technique is referred to as a "transfer burn" for reasons which the procedure will make plain.

After intravenous sodium-pentobarbitol anesthesia, one eye of the first rabbit, the transfer donor, is burned with 0.2 ml. of 1-percent sodium hydroxide and irrigated for 30 minutes with 0.85-percent sodium chloride, after which the animal is killed by intravenous air embolism. The superficial layers of the cornea—that is, epithelium and adherent substantia propria—are peeled from the entire anterior surface of the eye in one piece. This tissue is repeatedly punctured with the point of a scalpel and trimmed in the form of a cross. The perforation increases the opportunity for retained alkali to escape and the crosslike pattern provides tissue which will make good contact upon application to the normal eye of a second rabbit, the transfer recipient. Great care was exercised at all points to eliminate the possibility of alkali being carried by the instruments used.

The recipient is anesthetized and immobilized so that its head cannot be moved. The cross-shaped tissue from the

donor is placed with its center over the pupillary area of the recipient so that the burned epithelium is in contact with the normal recipient epithelium. This piece of tissue is kept in place for a one-hour period, during which time the lids of the recipient are held apart in order that the tissue will not be disturbed nor tears flush the pupil. The transfer tissue is prevented from dehydration by the addition of 0.01-ml. amounts of distilled water as required.

After a one-hour contact period, the recipient is killed by air embolism, and the transfer tissue from the donor is removed and tested with meta-cresol-purple indicator to ascertain whether it still contains alkali. A 5- by 5-mm. piece of recipient corneal tissue which has been in intimate contact with donor tissue is then peeled off and likewise tested with the indicator in a sealed hanging-drop preparation. Repeated trials with this method resulted in the colorimetric demonstration of alkali in or upon the recipient corneal epithelium when tissue was taken from over the pupillary area where contact with the donor tissue had been most intimate. The colorimetric demonstration of alkali may fail if small pieces of corneal tissue about 1 by 2 mm. in size are removed and tested individually. This failure may be due to the fact that the alkali present in such a small piece of tissue is insufficient to cause a color change in the relatively large drop of indicator solution used, or that all portions of the recipient cornea are not uniformly burned with alkali. Roughly indential pieces of corneal tissue removed from the untouched control eye of the recipient always produced a yellow color with the indicator, which denotes pH 7.6 or less, whereas the treated recipient cornea produced a purple color, indicating pH 8.2 or above. The indicator must be accurately adjusted to the midpoint of its

range or the minute amounts of alkali present in the recipient cornea may not be sufficient to effect the color change.

To serve as a control on manipulative procedures, the test was carried out with the use of normal donor tissue instead of that burned by sodium hydroxide, but with entirely negative results. All tissue tested remained acid to the indicator. Earlier attempts at fluorescein staining of recipient cornea were abandoned as a means of detecting the presence of injury caused by the transfer of alkali when it was discovered that all rabbit eyes show a punctate staining of the cornea after 20 seconds' contact with 5-percent fluorescein under slitlamp observation, although macroscopically they were not visibly stained. This type of staining could not be demonstrated in normal human eyes when the same fluorescein stain was used. The recognition of this fact forced reliance upon indicator solutions for the demonstration, for the burns produced by the transfer method were so minute that direct slitlamp observations without fluorescein staining were not considered reliable. A further objection to the use of fluorescein at this point is that it would not distinguish between mechanical injury and chemical injury from alkali. On one occasion, a small opacity which persisted for 24 hours was noted, but the use of the indicator remained the method of choice. The presence of alkali was also demonstrated after the recipient's cornea was washed for about 5 seconds with distilled water before removal for testing with the indicator.

In view of the demonstration of increased hydroxyl-ion content of the aqueous humor following severe burns with sodium hydroxide, it was thought advisable to attempt a transfer burn by using aqueous humor taken from a burned eye. The procedure was essentially the same

as has been described except that aqueous humor was aspirated by means of a syringe and 26-gauge needle from both the burned and normal donor eyes and was applied dropwise every 5 minutes for 1 hour to one eye on each of two recipients. This procedure resulted in the action of aqueous humor from the donor's burned eye being compared with that from the donor's normal eye which served as a control. Slitlamp observation of both recipients' eyes showed no visible damage. The eyes were then flooded with distilled water for 5 or 10 seconds to remove any of the aqueous humor adhering to the surface. Colorimetric tests revealed that portions of the cornea removed from these eyes after the animals were killed did not differ from their normal untreated eyes. This demonstration indicates the probable buffer action of the aqueous humor which had been shown by electrometric determinations to have an increased hydroxyl-ion content.

DENUATION

The outstanding success accomplished by simple denudation of burned corneal tissue in the treatment of human eye burns is reported by McLaughlin.¹ The application of this technique to the treatment of controlled experimental burns of the rabbit cornea did not produce comparable results in our hands. It required three days for a normal rabbit eye to heal after it had been denuded by the cottonswab method following the instillation of 4-percent cocaine hydrochloride. This interval is about three times as long as it required for the regeneration of human corneal epithelium. Numerous controlled experiments that compared denudation and no treatment led to the conclusion that in dealing with the rabbit cornea any mechanical interference will retard rather than foster the natural healing process. Despite the quantitative differences in

structure previously mentioned, observation has shown that the rabbit eye has enormous regenerative power following very severe damage and that injury to Bowman's membrane does not always result in scar-tissue formation as is the accepted fact in the case of burns of the human eye although it now appears that its corneal epithelium regenerates slowly.

Although species difference prevented the confirmation of McLaughlin's findings when using the rabbit eye, his consistently successful results amply justify his recommended therapy.

CONCLUSIONS

Experiments have been made upon corneal burns in the rabbit intended to assist in the therapy of human corneal burns in industry. The results of this work point to certain conclusions.

1. It is possible to grade the ability of fluid and dissolved chemicals to injure the cornea on the basis of application of a series of volumes and concentrations to the rabbit eye. The results correlate well with clinical experience in a plant handling a wide variety of compounds.

2. Alkaline molecules reaching the cornea are bound in some fashion to the epithelial cells and are not removed by prolonged washing with saline or water. Alkali bound in this fashion will be liberated from excised epithelium to injure intact epithelium in contact with the former. Presumably alkali is slowly liberated from its original site of fixation in the living eye to injure neighboring cells and result in a progressive burn.

3. Attempts to neutralize alkali on the cornea by prolonged flushing with dilute citric-acid solutions result in seriously aggravating the condition of the eye. Similar attempts to neutralize acetic-anhydride burns with milk-of-magnesia applications are less spectacularly harmful but they are not beneficial.

4. Alkali contacting the cornea penetrates it to a sufficient extent to raise the pH of the aqueous humor and threaten internal ocular structures.

5. The treatment of alkali burns upon rabbit cornea by denudation failed to demonstrate its effectiveness owing apparently to species differences in the rate of epithelial regeneration.

FURTHER OBSERVATIONS ON AQUEOUS VEINS*

K. W. ASCHER, M.D.

Cincinnati, Ohio

Although the site of exit of the intraocular fluid has been discussed for many decades, the actual elimination of the aqueous humor was biomicroscopically observed in May, 1941.¹ In, or beneath, the conjunctiva of normal human eyes, I chanced to see small, almost or completely colorless vessels emerging from the depth of the corneal limbus or from the limbal meshwork or from a scleral emissarium. When they joined episcleral or conjunctival veins, these clear vessels produced a more or less marked dilution of the blood streaming through these veins; often they continued to transmit a layer of clear fluid into the vein they had joined. I proposed to name these vessels, "aqueous veins," assuming that they were biomicroscopically visible pathways carrying intraocular fluid from Schlemm's canal and the deep scleral venous meshwork to the episcleral, conjunctival, and anterior ciliary veins.

Leaving the canal of Schlemm, the aqueous humor may rapidly and completely mix with the blood contained in the scleral venous meshwork (fig. 1), in which case, no clear fluid becomes visible in any of the conjunctival or subconjunctival veins. If and where, however, aqueous humor passes through the scleral meshwork without being mixed with blood, or accepting only a small amount of blood, clear fluid will become discernible (figs. 2, 3, 4). (See also table 1.)

While many ophthalmologists have had difficulty in recognizing the aqueous veins, others have confirmed their occurrence and significance. Some of these confirmations came a short time after the discovery of the biomicroscopically visible intraocular-fluid elimination was published, some later.

Vail became familiar with the aqueous veins soon after their detection and emphasized their importance.² Troncoso³ recognized the aqueous veins as an anatomic-physiologic fact. Verhoeff⁴ was the first to raise the farsighted question as to whether, with high intraocular pressure and a normal filtration angle, the clear stream in the aqueous veins would become longer. This question could not be answered immediately. Further observations on glaucomatous eyes⁵ showed that, in primary compensated glaucoma, the flow of aqueous is less vigorous and that it may become stronger after successful treatment with miotics or after successful surgery. Berliner⁶ referred to the aqueous veins without espousing their cause; this may be explained by the fact that, according to his references, only the preliminary note about the aqueous veins was used and that a more extensive discussion⁷ could not yet be considered for the manuscript of his textbook. Sugar⁸ and Gartner⁹ were able to see the aqueous veins, the latter even succeeded in photographing them. It is not easy to obtain satisfactory photographs of the aqueous veins proper, for they are only 0.01 to 0.1 mm. in diameter,^{1, 10} and, since they are mostly colorless trails, contrast but little with the surrounding sclera. The recipient vessels, characterized by their stratification, are more easily observable by means of both

biomicroscopy and photography.

Among those who have seen the aqueous veins but have not as yet published

their observations, I should mention Kronfeld,¹¹ Rohner,¹² and Weve.¹³

Although I was able to see the aqueous veins in about every fourth, and later in every third eye of all normal eyes that came under my observation, Gartner⁹ found them in 20 percent, and Goldmann¹⁰ in 75 percent of persons examined. Most of the aqueous veins that I have seen were located in either eye between the 2- and the 4-o'clock positions or between the 8- and the 10-o'clock positions in, or at a short distance from, the corneoscleral limbus. Goldmann¹⁰ found the aqueous veins mostly in the lower temporal or in the lower nasal quadrants. He, as well as Gartner,⁹ confirmed the stratification or layering of aqueous and sanguineous fluid running in the same vessel and forming two or three or more parallel strata. Both observed changes of this stratification following experimental manipulations. Changes in the blood-aqueous ratio which occur in aqueous veins after compression (figs. 5, 6) of their recipient vessel (see ref. 1, p. 36; ref. 5, pp. 1077-1084; ref. 7, pp. 1193-1198) were confirmed by Sugar,⁸ Gartner,⁹ Goldmann,¹⁰ and Kronfeld.¹¹ After compression of the recipient vessel, Goldmann more often observed an influx of

Fig. 2 (Ascher). Aqueous vein: ORIGIN IN LIMBAL LOOPS. *Diagram:* Having left the canal of Schlemm (7), clear fluid may pass the scleral meshwork (13) and, if not mixed with blood, may become visible in the limbal capillaries (14). *Drawing:* At the point E, the color of the vein abruptly changes to a very pale pink, proving the entrance of an aqueous vein from the depth of the limbus.

clear fluid (I had called this the positive glass-rod phenomenon), whereas Sugar⁸ and Gartner⁹ more frequently saw an influx of red blood cells into the aqueous

backflow of blood into the canal of Schlemm. Goldmann¹⁰ corroborated Sugar's conclusions, and mine, that the observations made on aqueous veins prove

Fig. 3 (Ascher). Aqueous vein: ORIGIN IN SCLERAL TISSUE—the most common type of aqueous-vein origin. *Diagram*: Clear fluid, if not mixed with blood, may become visible in a spiral or U-shaped arch, one limb of which emerges out of the scleral tissue. *Drawing*: The peripheral limb of the U-shaped arch ascends into the conjunctiva to join a conjunctival vein and to form a stratified current.

Fig. 4 (Ascher). Aqueous vein: ORIGIN FROM SCLERAL EMISSARIUM. *Diagram*: Having passed a part of the scleral meshwork, clear fluid may become visible in a scleral emissarium (19). *Drawing*: The largest aqueous veins are found among those originating from a scleral emissarium.

vein (the negative glass-rod phenomenon). Anatomic differences in individual eyes are, most probably, responsible for this apparent discrepancy (see ref. 5, p. 1084).

Sugar¹⁴ expressed the opinion that the presence of the aqueous veins gives evidence for a through-and-through circulation of the aqueous humor, and that their presence also explains why the application of the gonioscopic contact lens may cause

that there is a continuous elimination of aqueous humor taking place via the canal of Schlemm and the episcleral veins. Goldmann (ref. 10, p. 152) also agreed to my computation of the amount of aqueous humor eliminated by the aqueous veins. Considering the figures published about the diameters of the outlets of Schlemm's canal and those pertaining to the speed of movement in conjunctival vessels, I reached an approximate accord

between the amount of fluid possibly eliminated by aqueous veins and the estimations published in the literature (ref. 7, p. 1192).

Soon after the discovery of the aqueous veins, spontaneous as well as provoked pulsations were observed. These pulsa-

adrenalin solution into the conjunctival sac.

Some of the pharmacologic effects which I have described¹⁵ were confirmed by Gartner⁹ and by Goldmann.¹⁰ Gartner published photographs showing aqueous veins before and after administration of

TABLE 1
A PHYSIOLOGIC UNIT: THE CANAL OF SCHLEMM AND THE AQUEOUS VEINS

	Canal	Aqueous Veins
Embryology	Common primordial anlage (Sondermann, Ida Mann)*	Common primordial anlage
Anatomy	"Outer channels" connect Schlemm's canal with anterior ciliary veins (Schlemm, Leber, Maggiore, Troncoso, Henderson, Theobald, Friedenwald)	"Outer channels" connect Schlemm's canal with anterior ciliary veins
Physiology	Elimination of aqueous humor (Leber, Lauber, Troncoso, Seidel, Friedenwald)	Elimination of aqueous humor
Contents	Aqueous humor mixed with blood in varying proportions (Trantas, Salzmann, Troncoso, Friedenwald)	Aqueous humor mixed with blood in varying proportions
Distribution of contents	Stratification may occur (Troncoso)	Stratification very common
Changes in blood—aqueous ratio	Very common (Sugar, Bangerter & Goldmann, Kronfeld)	Very common
A. With increase of venous pressure	Backflow of blood into the canal (Bangerter & Goldmann)	Negative glass-rod phenomenon; i.e., blood enters the aqueous veins
B. With increase of aqueous pressure	Expulsion of blood from the canal (Kronfeld)	Positive glass-rod phenomenon; i.e., expulsion of blood from the aqueous veins
C. With decrease of aqueous pressure	Backflow of blood into the canal (Barkan, Kronfeld)	Negative glass-rod phenomenon; i.e., blood enters the aqueous veins

* For references quoted in this table see previous publications. (1,5,7)

tions were synchronous with the radial pulse and consisted of minute changes in the position of border lines separating the aqueous and the sanguineous phases, respectively (see ref. 1, p. 36; ref. 7, pp. 1201-1203). Goldmann¹⁰ confirmed the observation of these pulsating border lines and found that the peak of the clear-fluid influx was slightly delayed as compared to the radial pulse. He was able to increase these pulsations by instillation of

miotics. He confirmed my observation that miotics may markedly reduce the red-blood-cell content of an aqueous vein (see ref. 15, pp. 1302-1303; ref. 16, p. 1313). Goldmann¹⁰ reported the effects of adrenalin administration on aqueous veins corresponding to my observations (ref. 15, pp. 1304-1306).

While Verhoeff⁴ assumed a relationship between the increase of intraocular pressure and the visible outflow of aque-

ous humor, Gartner⁹ expressed the opinion that damage to an aqueous vein during an operation for glaucoma might have considerable influence on the intraocular pressure. Therefore, he determined to locate the aqueous veins of glaucoma patients in order to avoid injuring these important structures during surgery.

1075-1077 and 1079-1087; ref. 16, pp. 1309-1314) a working hypothesis was evolved, an hypotheses which, it is to be hoped, may be confirmed by future histologic investigations. I assumed that transient or permanent narrowing in the outlets of Schlemm's canal may be the cause for the failure of glaucomatous eyes

TABLE 2

A UNIT OF CLINICAL SIGNIFICANCE: THE CANAL OF SCHLEMM AND THE AQUEOUS VEINS

Condition	Gonioscopy of the Canal Shows	Biomicroscopy of the Aqueous Veins Show
Inflammation	Blood enters the canal (Trantas, Salzmann, Koeppe, Troncoso)*	Aqueous veins filled with blood; therefore, not discernible
Congestion	Blood enters the canal (Schlemm)	Aqueous veins filled with blood; therefore, not discernible
Primary compensated glaucoma	Blood rarely enters the canal (Bangerter and Goldmann, Kronfeld). Wessely effect inverted	Negative glass-rod phenomenon; i.e., blood enters the aqueous vein after compression of the recipient vessel
Decompensated glaucoma	Not yet studied	Aqueous veins carry blood from posterior uvea; therefore, not discernible
Secondary glaucoma	Wessely effect present (John)	Mostly negative glass-rod phenomenon
Controlled glaucoma	Blood enters the canal (Kronfeld and assoc.)	Sometimes positive glass-rod phenomenon; i.e., clear fluid expells blood from aqueous vein after compression of the recipient vessel

* For references quoted in this table see previous publications. (1,5,7,16)

Because of the wide areas treated when operating by cyclodiathermy, the damage which this procedure might cause to the aqueous veins is of particular concern to Gartner. He advised that the aqueous veins be undisturbed during any operation for the relief of glaucoma. Goldmann¹⁰ stressed the significance of the rapid outflow of aqueous humor, as observed biomicroscopically, for an understanding of the mechanism of such operations (table 2).

AQUEOUS VEINS IN THE ETIOLOGY AND CLASSIFICATION OF GLAUCOMA

From a cursory discussion of the role of the aqueous veins in the etiology and pathogenesis of glaucoma (see ref. 5, pp.

to show the backflow of blood into the canal, as observed gonioscopically by Bangerter and Goldmann.¹⁷ In some cases, changes in these outlets may even be the primary cause for the increase in intraocular pressure (figs. 7, 8).

In order to discuss the role of aqueous veins in the etiology of glaucoma, we may use Sugar's¹⁴ classification of glaucoma. Between the groups "failure of osmotic forces" and "mechanical closure of the chamber angle," it may be justifiable to insert: "occlusion of aqueous veins by different pathologic conditions in the limbal region." These conditions include keratitis, scleritis, tumor growth, and a possible idiopathic narrowing of the outlets of Schlemm's canal. Cases of appar-

ently primary glaucoma caused by this narrowing of the outlets should be classified as secondary glaucoma.⁵ (Table 3.)

In the group designated glaucoma secondary to cataract surgery, a blocking of aqueous veins by scar formation adjacent

merous outlets of Schlemm's canal seem to be available for intraocular-fluid elimination; even if all outlets situated along the incision should become obliterated by scar formation, those situated in the unsevered part of the limbus still could

Fig. 5 (Ascher). POSITIVE GLASS-ROD PHENOMENON. *Diagram:* After compression of the recipient vessel, clear fluid enters the blocked section and, in a reversal of current direction, expels the blood corpuscles from the recipient vessel (note arrows in drawing). Expulsion of red cells is the essence of the positive glass-rod phenomenon. *Drawing:* A large, pale vessel runs along the nasal lower limbus and eventually joins a regular conjunctival vein. Immediately after compression, practically all red blood cells leave the pale vessel and the adjacent section of the recipient vein. Both become as clear as water. The red blood cells retreat in an upward direction (note arrows).

Fig. 6 (Ascher). NEGATIVE GLASS-ROD PHENOMENON. *Diagram:* After compression of the recipient vessel, red blood cells enter the aqueous vein in a direction opposite to that of the previous aqueous flow. Blood may enter the canal of Schlemm (7). *Drawing 1:* At the 7-o'clock position, near the limbus, an aqueous vein joins its recipient vessel to form stratified current. *Drawing 2:* After compression of the recipient vessel, the stratification disappeared and the red blood cells entered the aqueous vein in a direction opposite to that of the previous aqueous flow (note arrows). Entrance of red blood cells into the canal of Schlemm is probable.

to the cataract incision is to be considered a possible cause of secondary glaucoma. In such a case, the increase of intraocular pressure may not, or at least not solely, be due to mechanical closure of the chamber angle. Along the corneoscleral limbus, nu-

continue to eliminate aqueous humor. In border-line cases, however, where intraocular pressure is near the upper limit, severing of a part of the outlets during surgery may suffice to produce a postoperative increase of intraocular pressure.

Up to the present time investigators have not ascertained whether or not all of the 20 to 30 outlets of Schlemm's canal are equal in physiologic value. Anatomic differences, as demonstrated by Theobald, are rather definite,¹⁸ with diameters of the single outlets varying between 5 and 50 mikrons, that is, in a ratio of 1 to 10. It seems reasonable to assume that an outlet measuring 50 μ in diameter will be more important for the in-

Schlemm. It is possible that, in some eyes, a great number of outlets are constantly eliminating aqueous humor; whereas, in other eyes, only a few outlets or even only one outlet may carry the main bulk of it (ref. 7, p. 1192).

In eyes of the latter type, surgical or traumatic severing of one of these main channels may initiate a disastrous increase of intraocular pressure. Gartner⁹ seems to have been the first surgeon who paid at-

FIG. 7

Fig. 7 (Ascher). BLOOD MAY ENTER SCHLEMM'S CANAL in the presence of any of the following conditions: Inflammation (Salzmann, Trantas, Troncoso); rubeosis iridis (O. Kurz); strangulation (Schlemm); pressure of the gonioscopic lens (Sugar, Bangert and Goldmann); decrease of intraocular pressure (Kronfeld and associates). Although Schlemm's canal has been thought to contain either colorless fluid or blood, considerable evidence has accumulated that it may contain separated layers of each of them.

FIG. 8

Fig. 8 (Ascher). GLAUCOMA AND BACKFLOW OF BLOOD INTO THE CANAL OF SCHLEMM. In eyes with normal intraocular pressure, blood easily enters the canal of Schlemm and most probably does so during the negative glass-rod phenomenon. In eyes with primary compensated glaucoma, aqueous veins fail to show the positive glass-rod phenomenon. Gonioscopically, entrance of blood into the canal should be expected. Bangert and Goldmann, however, stated that in glaucomatous eyes blood rarely entered the canal. They found: In 50 eyes with normal intraocular pressure, 20 eyes showed backflow into the canal, whereas in 40 glaucomatous eyes, only 2 eyes showed the backflow. Backflow into the canal is more common in eyes with normal pressure. Narrowing of the outlets (11) may cause the absence of backflow into the canal and the absence of the positive glass-rod phenomenon in eyes suffering from primary compensated glaucoma.

traocular-fluid elimination than another outlet only one tenth as large. Presence or absence of visible fluid elimination in human eyes may well be due to differences in the size of the outlets in different individuals. The location of the visible fluid elimination, that is the site of an individual aqueous vein, most probably also depends mainly upon the size of the single outlet from the canal of

tention to the possible danger connected with damaging an aqueous vein during an eye operation.

Engorgement of the venous drainage as a possible cause of glaucoma has been discussed in a previous publication (see ref. 16, p. 1310). The possible influence of local, as well as systemic, increase of venous blood pressure on intraocular pressure was discussed, and the role of

the aqueous veins in pulsating exophthalmos and in facial hemangioma was mentioned along with the importance of aqueous veins for the fluid elimination in hydrophthalmic eyes.

Sugar stressed the fallacy of consider-

sideration that early signs of congestion may be found in practically every case of compensated glaucoma under biomicroscopic examination of the aqueous veins (see ref. 5, pp. 1076-1077). This certainly does not mean that the clinically so im-

TABLE 3
CLASSIFICATION OF SECONDARY GLAUCOMA
Modified from Sugar's table (1942)

-
- A. Failure of Osmotic Forces
 - 1. Arteriosclerosis in afferent vessels of the canal of Schlemm
 - 2. Obstruction of trabecular spaces
 - a. Glaucoma capsulare of Vogt
 - b. Pigment accumulation

ing vascular congestion or lack of it as a criterion in the classification of glaucoma (see ref. 14, p. 329) and quoted Barkan as having the same opinion. This standpoint seems to be confirmed by the con-

portant distinction between compensated and congestive glaucoma should be disregarded. Its value for therapeutic decisions and for the choice of the operation cannot be overestimated. Fundamentally, how-

ever, it must be stated that, on biomicroscopic examination, early signs of vascular congestion are found in eyes suffering from an otherwise unquestionably compensated glaucoma (table 3).

AQUEOUS VEINS AS PATHWAYS OF DECOMPENSATION

Leber, Maggiore, and Theobald (see ref. 7) described collaterals, connecting both venous districts, which finally empty into the vortex veins and into the anterior ciliary veins, respectively. While the ma-

independent venous regions have rarely been mentioned in the glaucoma literature. They are, however, highly significant for the understanding of the mechanism of decompensated (or congestive) glaucoma (fig. 9).

With an increase in intraocular pressure, increasing quantities of blood that should leave the choroid by way of the vortex veins are forced into a collateral detour via the scleral plexus into the anterior ciliary veins. Thus, the venous return takes place partly through channels

Fig. 9 (Ascher). AQUEOUS VEINS AS PATHWAYS OF DECOMPENSATION. *Drawing:* With increase of the intraocular pressure, the vortex veins become compressed (note arrow). *Diagram:* With compression of the vortex veins, blood is forced into the scleral meshwork (12, 13). Here it assumes a direction opposite to that of the aqueous outflow (arrows).

jority of the veins of the human ciliary body are drained into vessels which finally empty into the vortex veins, a part of the veins that leave the ciliary muscle pierce the sclera and empty into the anterior ciliary veins. Although seen and described by Leber, these connections are not clearly visible in his well-known scheme which has been reproduced in almost every textbook of ophthalmology. They are better visible in Maggiore's and Theobald's illustrations, as well as in Duke-Elder's reproduction¹⁹ of Maggiore's drawing, and in the reproduction of the same drawing published by Rollin²⁰ in the French "Traité d'Ophthalmologie." These connections between two otherwise

which normally do not take care of blood deriving from the choroid. Years ago, Heerfordt²¹ discussed the possibility that increased intraocular pressure may lead to compression of the intrascleral part of the vortex veins, an assumption which emphasized the importance of vortex veins and of their connections leading to the anterior ciliary veins for an understanding of the mechanism of congestive glaucoma.²² He assumed that increase of intraocular pressure may exert a valve-like effect on the origins of the vortex veins, forcing blood that normally should leave the vortex vein backward and into the anterior ciliary veins. Although Heerfordt's theory was not given much consent

(mainly because his hypothesis regarding the alleged valve-like effect on the vortex-vein origin was not confirmed), the significance of the collaterals connecting both venous regions (the one draining into the vortex veins and the other, emptying into the anterior ciliary veins) cannot be questioned.

It may well be that the nonappearance of the positive glass-rod phenomenon^{5, 16} in glaucomatous eyes can be considered, at least in some of the cases, an early sign of congestion in the collateral pathways which connect the drainage system of the vortex veins with that of the anterior ciliary veins. This reflection, however, should not preclude consideration of a possible narrowing of the outlets of Schlemm's canal, as described previously (see ref. 5, pp. 1083-1087).

THE CLEAR FLUID OBSERVED IN AQUEOUS VEINS IS NOT PRODUCED BY A SKIMMING OF RED BLOOD CELLS

One question remains to be answered. It might be doubted that the clear fluid seen in aqueous veins really is aqueous humor, sometimes clear, sometimes mixed with varying amounts of blood. Another interpretation might have been proposed; namely, that in the narrow vascular passages surrounding the corneoscleral junction of the human eye, a mere skimming off of plasma from red blood cells may occasionally take place. In this case, the clear fluid observed in aqueous veins would be blood, deprived of all, or of a part of, its red cells. In other words, it would be plasma without, or with a subnormal content, of red cells. I have rejected this hypothesis (see ref. 7, p. 1185) because of the anatomically recognized connections between the canal of Schlemm, the intrascleral vascular meshwork, and the episcleral and conjunctival veins. The phenomena observed after compression of the recipient vessels also favor the as-

sumption that aqueous humor is present in the aqueous veins. Vail proposed to reach a final decision by using fluorescein as a tracer. Before I could start on experiments of this kind, Goldmann¹⁰ succeeded in demonstrating that the limpid fluid streaming in the aqueous veins was not plasma but aqueous humor. He performed experiments on persons whose aqueous veins were very distinct. Five c.c. of a 10-percent solution of uranin, which is identical with fluorescein, were injected intravenously. Goldmann made his observations of the aqueous veins by means of a slitlamp microscope with its rheostat maximally opened and with intercalation of a Corning ultraviolet filter. Whereas vessels containing blood soon showed a yellowish-green hue, the aqueous veins remained clear and colorless. In recipient vessels, Goldmann was able to distinguish two or more parallel strata, a greenish, sanguineous phase and a colorless, aqueous one. Using a 20-diameter magnification, he saw a uniform greenish color only after a complete mixing of the aqueous and sanguineous phases, which took place a few millimeters beyond the junction of the aqueous vein and its recipient vessel.

Goldmann's observations, performed after intravenous uranin injection, proved that the aqueous veins contain intraocular fluid and not plasma, partly or completely deprived of red blood cells. After intravenous administration, uranin circulates with the blood, confined to the plasma. It would appear even in skimmed up plasma. Therefore, the lack of color in aqueous veins after intravenous administration of uranin leads to the conclusion that these vessels do not contain blood deprived of red blood cells but intraocular fluid with varying amounts of blood.

The response of animal and human eyes to oral and to parenteral fluorescein administration has been studied by several investigators. The most exact figures

seem to be those reported by Lindner²³ who, after oral administration of 4 gm. of uranin, observed normal human eyes with the aid of the corneal microscope. The interval between administration of the dye and its appearance in the anterior chamber was 15 to 30 minutes; the highest intensity of the green hue, however, was found 1½ to 2 hours after intake of the dye. This maximum lasted for one to two hours, and the complete resorption of the green color from the anterior chamber did not take place before one, or even two, days had elapsed. Using colorimeter tests, Lindner stated that the uranin concentration in the aqueous humor reached 1:8,000,000 to 1:3,000,000. In the initial stages of the experiments, the concentration of uranin was markedly higher in the blood as compared to that in the aqueous humor; later on, however, the uranin level of the aqueous humor surpassed that of the blood.

These observations would indicate that it is imperative to perform experiments, similar to Goldmann's, soon after the administration of uranin, especially if the dye is introduced intravenously; for by this method the interval between the administration of the dye and its entrance into the anterior chamber is shorter as compared to the interval observed after oral intake. In albinotic eyes, the green color appears in the anterior chamber while the uranin injection is being performed.¹³ The fact must be considered that uranin will pass through the blood-aqueous barrier twice: first, from the capillaries into the aqueous humor; then, from the aqueous humor into Schlemm's canal and possibly into intraocular capillaries which finally will return the dye into the venous circulation. If the wait is too long, it may be possible to see green color in the aqueous veins and none in the regular veins, indicating the resorption of the dye via the canal of Schlemm and the

intrasccleral meshwork. Up to the present time, this phenomenon has not been described.

Goldmann¹⁰ performed another important experiment to show that the contents of the aqueous veins are really aqueous humor and the aqueous veins are accessible from the anterior chamber of the human eye. In repetition of the famous animal experiments performed by Seidel (see ref. 7), Goldmann injected India ink into the anterior chamber of an eye that was to be enucleated because of a uveal sarcoma. Previous to the injection of the ink, an aqueous vein was located in the nasal episcleral region of that eye. After the instillation of a cocaine solution and the aspiration of a small amount of the aqueous humor contained in the chamber of the sarcomatous eye, an ana-partes mixture of saline solution and Guenther-Wagner Pertusche (a brand of India ink) was injected into the anterior chamber. The intraocular pressure was reduced after the injection of the ink and, although the regular episcleral vessels maintained their normal red color, the previously located aqueous vein showed a black tint.

Thus, for the first time, it was demonstrated that an aqueous vein could be filled with a material introduced into the anterior chamber. The most striking objection to Seidel's experiments using anterior-chamber injections was raised by Weiss who (see ref. 7) stated that this method could destroy natural barriers separating the anterior chamber from the canal of Schlemm or from intrasccleral veins, either during the preliminary aspiration of aqueous humor or during the injection of the dye. It is difficult to understand why this possible destruction should have occurred, in Goldmann's experiment, just on the site of the previously located aqueous vein which turned black while the regular episcleral veins

maintained their normal red color.

Both types of experiments (uranin administration and ink injection) prove that the aqueous veins are accessible from the anterior chamber, as well as that these veins really contain aqueous humor. They do not prove, however, that there is a free communication between the anterior chamber of the human eye and the canal of Schlemm.

VISIBILITY OF AQUEOUS VEINS WITHOUT THE USE OF THE CORNEAL MICROSCOPE

In most instances, the aqueous veins proper are too small to be recognized without the aid of the slitlamp microscope. Some of them, however,—namely, those that carry a stratified current and attain a diameter exceeding that of the smallest precapillaries—can be seen with a 10-diameter magnifying loupe under good focal illumination. Their size and the presence in the same vessel of a sanguineous and a clear phase make them readily recognizable with the aid of the loupe.

During the autumn of 1945 and the spring of 1946, 400 unselected patients with quiet eyes were examined for the presence of aqueous veins detectable without the corneal microscope. Of these patients (most of whom came in for a test of refraction) 57 showed aqueous veins when examined with the simple magnifying loupe. Thus, with the loupe 14.25 percent of all uncongested eyes were found to show aqueous veins; whereas, 26.78 percent showed them when observed under the slitlamp microscope.⁷

It should be mentioned that, with this method of examination, a recipient vessel might sometimes have been counted instead of an aqueous vein proper. The presence of a recipient vessel, however, always is indicative of the presence of an aqueous vein. It is, therefore, valid to assume as correct an estimate of 14.25 per-

cent for eyes showing aqueous veins (or at least recipient vessels) under loupe observation.

SEASONAL DIFFERENCES IN THE OCCURRENCE OF AQUEOUS VEINS

Although observation of the individual eye revealed the presence of one or of a few vessels charged with a continuous or intermittent elimination of aqueous humor (see ref. 1, p. 35; ref. 7, p. 1179), and although the same aqueous vein could be recognized after intervals ranging from a few months to 2½ years (see ref. 5, p. 1077),* the occurrence of the aqueous veins seemed to change with the seasons of the year.

The 400 patients mentioned were seen at different times of the year. Two hundred were examined during the months of November and December of 1945, and 200 during March and April of 1946. As has already been stated, these examinations were performed without the corneal microscope and with only a 10-diameter magnifying loupe under good oblique focal illumination. At this lower magnification, an average of 14.25 percent of easily visible aqueous veins (or at least recipient vessels of an aqueous vein) were observable. In the autumn group, however, the percentage of aqueous veins was only 10.0; whereas, in the spring group, it was as high as 18.5 percent.

The assumption that the occurrence of aqueous veins could vary seasonally does not explain this numerical difference. The histologic substrata of the visible intraocular-fluid elimination (see ref. 7, p. 1179) cannot possibly change with changes of climatic factors. What, however, may change is the degree of difficulty encountered in finding vessels differing in color from the regular conjunctival and subconjunctival veins. The visi-

* Since that time, aqueous veins have been observed up to a period of 4½ years.

bility of the aqueous veins and of their recipient vessels, may well be influenced by at least one of the climatic factors; namely, by seasonal differences in illumination (see ref. 7, p. 1200). An eye exposed to bright light often shows an increase of the clear fluid contained in its aqueous veins and, occasionally, even an increase of the speed with which the clear fluid is flowing in them; however, in many eyes, darkness produces the opposite effect—namely, an increase of the red-blood-cell content of the aqueous vein and, occasionally, a retardation of the flow in the aqueous vein. In this connection, I should mention that, in eyes blind from tabetic optic-nerve atrophy, I have often found an extremely slow movement of the fluid streaming in the aqueous veins. The greater degree of brightness of the sky during the months of March and April might be responsible for the greater ease of finding aqueous veins during these months than during the months of November and December. There may also be a connection between the ease of finding the aqueous veins and the occurrence of conjunctival diseases. The incidence of slight conjunctival irritations may be higher during the fall and early winter than in the spring; therefore, the well-known effect of conjunctival hyperemia on aqueous veins (see ref. 16, p. 1314) will make them appear less conspicuous, or even completely disappear, in those periods of the year when external factors favor the development of any kind of conjunctival hyperemia. This may serve to explain the difficulty encountered by some ophthalmologists in finding aqueous veins at all. In discussing the extremely rare observation of aqueous veins in the eyes of patients admitted to the Utrecht University Eye Clinic, Fischer¹³ agreed to my tentative explanation that, after so many months of starvation, the conjunctivas of all people coming to this Clinic

were more or less congested. Hyperemia in conjunctival or episcleral vessels tends to conceal the presence of aqueous veins by adding red cells to the clear stream. Therefore, anything that may increase the red-cell content in the aqueous veins will make recognition more difficult. If nutritional or climatic factors favor the incidence of even slight conjunctivitis cases, they may produce the impression of scarcity or even absence of aqueous veins by making the clear fluid indiscernible.

SUMMARY

In 1941, for the first time by means of the biomicroscope, aqueous humor was seen to stream through conjunctival and episcleral veins of the normal human eye. Vessels containing a clear fluid, sometimes mixed with varying amounts of blood, can be found in at least one third of all quiet human eyes with the use of the corneal microscope and slitlamp illumination. With the aid of a 10-diameter magnifying loupe and good oblique illumination, they are detectable in more than 14 percent of all eyes not injected. Emerging from the limbal meshwork, from the depth of the scleral tissue adjacent to the limbus, or from a scleral emissarium, these clear vessels join conjunctival or subconjunctival veins. In the recipient vessel, they produce either a marked dilution of its blood content or a characteristic pattern of stratification with two, three, or more differently colored layers that run parallel to one another along the vessel wall. The colorless vessels were termed aqueous veins. They are biomicroscopically visible pathways connecting Schlemm's canal and the intrascleral meshwork with conjunctival and subconjunctival veins. Not all quiet human eyes show aqueous veins owing to the fact that aqueous humor, upon leaving the canal of Schlemm, may become rapidly and completely mixed with the blood which is

contained in the intrascleral meshwork. If, however, clear fluid can reach the episcleral or conjunctival veins without the previous addition of too many red blood cells, an aqueous vein will become visible. Anatomic differences in the outlets of Schlemm's canal are rather definite, and it seems reasonable to assume that an outlet measuring 50 μ in diameter will be more important for the elimination of intraocular fluid than another outlet having only one tenth of this diameter. It is possible that, in some normal human eyes, a great number of outlets are constantly eliminating aqueous humor; whereas, in other eyes, only a few outlets or even only one, may carry the bulk of fluid. In eyes of the latter type, surgical or traumatic severing of one of these main channels may initiate a disastrous increase of intraocular pressure. The possible role of the aqueous veins in the etiology and classification of glaucoma was discussed. Observations on glaucomatous eyes led to the working hypothesis that a transient or permanent narrowing of the outlets of Schlemm's canal may be connected with the presence, or even may be responsible for the development, of increased intraocular pressure in certain eyes. Clinical observations and reflection suggest the significance of aqueous veins in the mechanism of decompensated glaucoma.

Many ophthalmologists have had difficulty in recognizing the aqueous veins; whereas, others have confirmed their occurrence and significance. Photographs of recipient vessels have corroborated the presence of highly diluted blood in these vessels, as well as the influence of drugs on the elimination of intraocular fluid through the aqueous veins.

Protracted observation of the veins surrounding the corneoscleral junction will always reveal that one or more individual

channels are continually charged with the elimination of intraocular fluid. Physiologic factors and climatic differences in part concur in their effect and in part exercise the opposite influence on aqueous veins. Once located, the particular aqueous vein remains discoverable at its original location after months and years, and retains its characteristic qualities. Apparent differences in the incidence of aqueous veins, when searched for with a 10-diameter magnifying loupe at different seasons of the year, are due to differences in the red-cell content and to the greater difficulty of recognizing an aqueous vein when there is conjunctival congestion. In eyes blind from tabetic optic-nerve atrophy, the movement of the fluid streaming in aqueous veins is often slow.

The question as to whether aqueous veins contain aqueous humor or blood deprived of all, or part, of its red cells, has recently been answered by Goldmann. He stated that, after intravenous injection of a 10-percent uranin solution, the aqueous veins remained colorless while the blood running in the recipient vessels, in conjunctival and in subconjunctival veins, showed the greenish-yellow hue of the dye. India ink, injected into the anterior chamber of an eye with a uveal sarcoma, appeared in a previously located aqueous vein only and not in any of the other vessels.

The physiologic and clinical significance of the aqueous veins should be acknowledged. The term aqueous veins should be accepted for the biomicroscopically visible part of the pathways which are charged with intraocular-fluid elimination from the canal of Schlemm via intrascleral meshwork to the conjunctival, subconjunctival, and anterior ciliary veins.

DISCUSSION

SIR STEWART DUKE-ELDER, chairman (London, England): I should like to thank Dr. Ascher for his able presentation—not only an exceedingly interesting subject, but very important, and a subject on which there ought to be some study.

I want to ask him one question. You started off by eliminating the arterial system entirely. Do you agree with Dr. Friedenwald that there are direct arterial aberrant vessels in the canal of Schlemm.

DR. ASCHER (closing): I do not dare to answer that question because I do not have any pertinent experience of my own.

From the papers published on this subject, I do believe that it is very possible that these vessels described by Friedenwald are not only present but that they also fulfill the physiologic function as described or ascribed to them by Friedenwald.

EXPERIMENTAL DINITROPHENOL CATARACT*

J. W. BETTMAN, M.D.

San Francisco

Cataract following the ingestion of dinitrophenol in human patients was first reported in 1935.^{1, 2} Within the following six years, 177 cases had been reported in the literature.³ The patients who developed dinitrophenol cataracts were obese, were almost all women, and were in a younger age group than those in whom cataracts were ordinarily seen.⁴ These facts suggest that variations in metabolism may be significant in the development of the cataracts.

Thorough experimentation on laboratory animals prior to the release of dinitrophenol for medical use was carried out by Tainter and his fellow workers at Stanford Medical School. Further careful work was done following the reports of dinitrophenol cataracts in humans. In no instance was it possible to produce cataracts in the ordinary laboratory animals (specifically rats, rabbits, guinea pigs, and dogs);⁵ nor was it possible to produce experimental cataracts on feeding dinitrophenol to animals deficient in vitamins A, B₂, or C.⁶ The incidence of cataracts could not be increased when dinitrophenol was administered in conjunction with such cataract-producing agents as lactose and galactose.⁷ These facts again suggested that variations in metabolism accounted for the failure of animals to develop dinitrophenol cataracts. It is significant that in all cases the species used were mammalian.

In 1944, Robbins⁸ reported that chickens and ducks on a diet of 0.25-percent

dinitrophenol developed marked lens opacities within eight hours. These lens opacities were sufficiently dense to be seen by the naked eye, although they cleared almost entirely within 24 hours after the dinitrophenol diet was started and while the birds were still on the 0.25-percent dinitrophenol diet. This work was quickly confirmed.⁹ The lens opacities were limited to the anterior and posterior subcapsular regions. The posterior subcapsular area was more densely opaque than the anterior. The nucleus and the remainder of the lens cortices remained entirely clear. No abnormalities other than in the lens were noted by slitlamp microscopy. The opacities developed in 100 percent of young chicks on the 0.25-percent diet, but with less regularity in older chickens on the same concentration of dinitrophenol.¹⁰ They even developed on concentrations of dinitrophenol as low as 0.05-percent, but with less frequency.

Now, at long last, experimental dinitrophenol cataracts had been produced, but they had been produced in avians, not mammals, and they were transient, not permanent.

EXPERIMENTS ON OBESE MICE

One of the significant facts in human patients who developed dinitrophenol cataracts is that they were all obese. In previous experimental studies, obese animals had never been used. To determine whether or not factors associated with obesity may play a part, a strain of congenitally obese mice was fed dinitrophenol. These adipose mice have been used for studies in obesity for the past 20 years.¹¹ The mice were all yellow, and

* Study conducted under a grant from the Francis I. Proctor Fund. Division of Ophthalmology, Stanford University Medical School, San Francisco. Read before the Association for Research in Ophthalmology, Inc., at San Francisco, July 2, 1946.

the gene for adiposity was apparently associated with the yellow color. They were all heterozygotes since the yellow gene is lethal when homozygous. In conjunction with the adiposity, and probably responsible for it, was a definite tendency for the yellow mice to eat more and be less active, as is often the case with adipose humans.¹² In all other respects, the obese yellow mice did not seem to differ from the ordinary nonobese varieties.

In this experiment, 40 fat, yellow mice were put on their usual diet of Tioga meal, but 0.1-percent dinitrophenol was mixed with it. Forty control fat, yellow mice were placed on the diet of Tioga meal without the dinitrophenol. The dosage of 0.1-percent dinitrophenol in the diet was selected because this was previously determined by Tainter¹³ as a concentration sufficient to decrease the growth rate and final weight without decreasing the life span of white rats. This concentration, therefore, was believed to be sufficient to affect the metabolism without being lethal to the yellow mice.

The animals used were 8 to 10 months old (younger middle age). They were examined by slitlamp microscopy before the experiment was started and at periodic intervals thereafter; they were weighed weekly. Many mice present fine, suture-line opacities that do not develop into immature or mature cataracts and occur regardless of skin color, weight, or diet. In the light of this fact, these fine, suture-line opacities were ignored.

Three of the 40 mice on the diet with dinitrophenol developed cataracts that were immature within four to eight weeks after the diet was started. These cataracts were first seen as fine posterior subcapsular opacities; then the nucleus became milky in association with the development of definite cortical spokes. No other pathologic changes were observed

in the eyes with the development of the cataracts. None of the 40 control animals from the same colony developed cataracts.

Although the incidence of three cataracts out of 40 animals on dinitrophenol (7½-percent) is admittedly small, this is comparable to the incidence of thallium cataract in rats, which is 11 percent.¹⁴ It is also comparable to the incidence of 7.4-percent cataracta raphanica in patients with ergot poisoning.¹⁵ The incidence of 7½-percent of dinitrophenol cataracts in congenitally obese yellow mice is definitely higher than the presumed incidence of dinitrophenol cataract in humans. This has been estimated to be 0.86-percent by Horner.⁵

The time of onset of the cataracts in the obese mice (four to eight weeks after the dinitrophenol was started) was also comparable to the time of onset of thallium cataract in rats (six weeks).¹⁴

In human subjects, cataract formation often occurred with dramatic suddenness some time after the dinitrophenol was discontinued. In order to determine whether or not a comparable phenomenon would occur in the congenitally obese mice the dinitrophenol was discontinued in 13 of the mice after six months of dinitrophenol diet. In no instance did cataract formation occur during an additional four months' period of observations.

EXPERIMENTS ON OTHER MICE

As previous experimental work with dinitrophenol feedings had been performed on mammals other than mice, it was necessary to demonstrate that cataracts did not develop in ordinary mice that were not obese. Twenty albino mice were put on a 0.1-percent dinitrophenol diet and 20 albinos were kept as controls. Twenty black mice were also placed on the 0.1-percent dinitrophenol diet, to rule out possible differences due to pigmentation.

tion. No cataracts developed except for one albino mouse which developed a cataract just before its death after 11 months of dinitrophenol feedings. This is not comparable to the cataracts which developed after only four to eight weeks in the younger mice.

The question logically arises as to why chickens are so much more susceptible to the formation of dinitrophenol cataracts than are the obese mice. Is this difference due to higher dosages of the drug used in some of the chickens? Is it due to the difference in age of the chicks and the mice, or is it due to differences in the temperatures of the two species? In an attempt to answer these questions, the following experiments were performed.

Although a 0.25-percent dinitrophenol diet is lethal to mice within a short time, experiments were undertaken to determine whether this dosage would produce cataract formation in mice within less than 24 hours as had occurred in chickens.

Six ordinary albino mice were put on a 0.25-percent dinitrophenol diet. They were examined before the diet was started and eight hours later. No cataract formation was present in any of the mice at this time. All six died shortly thereafter, as the dosage of 0.25-percent dinitrophenol was lethal. Six congenitally obese yellow mice were put on the same diet and examined at the same intervals. Their eyes also remained clear, and they likewise died shortly after the eight-hour period. We may conclude that 0.25-percent dinitrophenol does not cause rapidly developing cataracts in either obese or ordinary adult mice, although it did cause this type of cataracts in chicks.

In view of the fact that young chicks were more prone to develop cataracts than adult chickens, five-to six-week-old mice were also put on 0.25-percent dinitrophenol. All eight of the mice were free of cataracts nine hours after the diet

was started. The 0.25-percent dinitrophenol diet was continued for one week, and repeated observations were made during this time. At the end of this period, two of the mice had died, but all were free from cataract formation. The age of the mice, then, did not seem to be a factor in the development of the type of cataract observed in chickens on a dinitrophenol diet.

EFFECTS OF TEMPERATURE

The normally higher avian body temperature suggested that this may have been a factor in the predisposition of the chicks to cataract formation while on a dinitrophenol diet. It had already been shown that the toxicity of 2:4 dinitrophenol on mice is increased by raising the environmental temperature to 40°C. and lowered by decreasing the environmental temperature to 6°C.¹⁶ Accordingly, 10 congenitally obese yellow mice were placed in an incubator with the environmental temperature kept at 38 to 38.8°C. Five of the group of 10 mice were also put on a diet of 0.25-percent dinitrophenol, while the other five were kept in the incubator on a normal diet as controls. The body temperatures of the incubated mice on DNP were variable but tended to be higher than the readings noted in other group. After eight hours of incubation of both groups, neither the one on dinitrophenol nor the one without it developed cataracts upon examination by slitlamp microscopy. All of the mice subjected to both incubation and dinitrophenol died shortly thereafter and, consequently, the experiment could not be continued. Differences in temperature, then, did not seem to be the factor which accounts for the difference in the susceptibility of mice and chicks to transient cataracts.

One cannot draw definite conclusions from an experiment in which only 3

of 40 obese mice developed cataracts in two months or less. Nevertheless, the absence of cataract formation in thin mice (except one moribund mouse which had been on therapy for almost a year) suggests that obesity may be a definite factor in cataract formation associated with dinitrophenol therapy. It was necessary to work with relatively small numbers of mice because of the need of numerous time-consuming slitlamp examinations.

As previous studies had demonstrated that chicks on a diet of 0.25-percent dinitrophenol developed a transient cataract within eight hours, the question naturally arises as to why the chickens are markedly susceptible to a transient dinitrophenol cataract, whereas obese mice are slightly susceptible to a permanent dinitrophenol cataract, and other mammals are not at all susceptible. It was not the dosage, since chicks develop cataracts on concentrations as low as 0.05-percent, although with less regularity, and mice do not develop the cataracts on concentrations as high as 0.25-percent. It is not the age factor, because old chickens do develop dinitrophenol cataracts, whereas young mice on comparable doses do not develop them. It probably is not the higher body temperature of avians, for mice placed in an environmental temperature of 38° to 39°C. did not show cataracts while on the 0.25-percent dinitrophenol diet.

It may be that the transient opacity in the chick is due to a relative anoxia produced by the dinitrophenol, since dinitrophenol increases the oxygen consumption. Cataracts have been produced in a decompression chamber in rats and rabbits.^{14a} It may be that this effect is due to an increase in the lactic acid, which was also demonstrated under these circumstances. One may speculate that this produces a colloidal change which has

not gone far enough to be irreversible.

DIRECT INJECTION EXPERIMENTS

We now may ask the question: Is the transient cataract produced in chicks by dinitrophenol a direct effect of the drug on the lens, or it is due to some product, toxic to metabolism, resulting from the ingestion of dinitrophenol? Is there a difference in susceptibility of the avian lens and the mammalian lens to dinitrophenol cataract, or is this apparent difference due to factors elsewhere than in the lens?

To answer these questions, sodium 2:4 dinitrophenol was injected into the anterior chambers of young chickens. Dense anterior subcapsular cataracts were found 20 to 40 minutes after the direct injection of the dinitrophenol. The solutions of dinitrophenol had been rendered isotonic and buffered to pH 7.3, and were used in dilutions of 1:1,000, 1:5,000, and 1:50,000. A control solution of the agents used to attain isotonicity and the buffered state was injected into the opposite eye of each chick and in no instance did a cataract occur. The average quantity used was 0.04 c.c., and the injection was preceded by withdrawal of the same amount of aqueous. The cataracts were exceedingly dense when unbuffered 1:1,000 dinitrophenol was used; somewhat less dense when buffered 1:1,000 dinitrophenol was used; and even less dense, but very definite, when the buffered 1:5,000 solution was used. The 1:50,000 solution did not cause cataracts when injected in the usual quantity of 0.03 to 0.05 c.c.

Twenty-four hours after the injection these lens opacities had cleared almost completely. Seventy-two hours after the injection, the lenses were entirely clear.

EXPERIMENTAL PROCEDURE

Four- to eight-weeks-old, white-leghorn female chicks were used. The eyes were examined

by slitlamp microscopy preceding the injection and were found to be clear in all instances. The chicks were anesthetized with ether, and 0.5-percent tetracaine drops were instilled locally. After puncture through the cornea with a 30-gauge needle and a tuberculin Luer without injuring the iris or lens, 0.03 to 0.05 c.c. of aqueous was withdrawn. Through the same corneal-puncture wound, 0.03 to 0.05 c.c. of the sterile solutions described above was injected. The chickens were examined by slitlamp microscopy at intervals of 15 minutes after the injection for the first two hours, and again in 24 hours and 72 hours.

Within the first 15 minutes, no lens changes were found, but the secondary aqueous was cloudy in both the eyes injected with the dinitrophenol and those injected with the buffer solution used as a control. Approximately 30 minutes after the injection, the dinitrophenol-instilled eyes revealed definite anterior subcapsular opacities. These increased in the succeeding 15 to 30 minutes and then remained unchanged. In some instances a fine posterior subcapsular opacity appeared to be present, but the remainder of the lens was always clear. Twenty-four hours after the injection, the lenses were almost entirely clear except for a very fine anterior subcapsular opacity in some instances. Seventy-two hours after the injection all lenses were entirely clear. In no instance did the control eye exhibit any lens changes.

The buffer-control solution and buffered-dinitrophenol solutions were prepared by the Barnes-Hind Laboratories of San Francisco, as follows:

1. A phosphate buffer solution of pH 7.3 was made according to the following formula:
Sodium acid phosphate ($\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$)

Disodium phosphate (Na_2HPO_4)	1.747 gm.
Sodium chloride	7.653 gm.
Distilled water q.s.	3.90 gm.
pH adjustment: 7.3 plus or minus	1,000 c.c.
0.02 pH unit	(24°C.)

Freezing point depression -0.569°C .

2. Sodium dinitrophenol solutions: The following concentrations of sodium dinitrophenol were prepared in the above buffer:

- a. 1:1,000
- b. 1:5,000
- c. 1:50,000
- d. 1:200,000

Preparation: A 1-c.c. ampul was filled with these four concentrations and also a 1-c.c. ampul containing the phosphate buffer alone as controls. The sealed ampuls were autoclaved at 120°C . for 20 minutes for sterilization. Ampuls from each concentration were checked for sterility on thio-glycolate media. All cultures were negative.

It is of interest to compare the concentration of dinitrophenol, which caused a definite cataract when injected into

the anterior chamber, with the concentration probably attained after ingestion of sufficient dinitrophenol to cause a definite cataract in the chick. Direct injection of 0.04 c.c. of 1:5,000 dinitrophenol solution consistently produced a cataract. The ingestion of 110 gm. of 0.25-percent dinitrophenol by a 440-gm. chick likewise consistently produced a cataract. If all the dinitrophenol were absorbed, and if it were equally distributed throughout the body, a concentration of 1:1,600 would result. As complete absorption and equal distribution are extremely unlikely, it is probable that the concentration produced by direct injection and by ingestion are similar.

In the light of the fact that dinitrophenol produces cataract by direct injection, and that the concentration which causes cataracts by this method (1:5,000) is comparable with the concentration resulting from ingestion (1:1,600), it is suggested that the effect of dinitrophenol upon the chicken lens is a direct action not dependent upon any intermediate product of metabolism.

It next remained to be determined whether the failure to obtain cataracts from dinitrophenol in most mammals was due to a difference in the reaction of the lens itself to the dinitrophenol or to a difference in the metabolism of dinitrophenol in the mammal as compared with the avian species. The direct injection of dinitrophenol solutions into the eyes of rabbits was, therefore, performed. The injections were done in precisely the same manner as described in connection with the chicks, except that a larger quantity (+0.10 c.c.) was injected, because the anterior chambers were larger. The same type of anterior subcapsular cataract occurred in the same length of time and cleared completely as was the case with the chicks, although the opacity

was not quite so marked in the rabbits as in the chicks.

Rabbits, as well as other mammals, had previously been subjected to feeding experiments with dinitrophenol and, in all cases, no cataracts developed. In order to confirm the absence of cataract formation in rabbits, when fed the same concentration of dinitrophenol as chicks, rabbits were placed on a diet of 0.25-percent dinitrophenol. Although this concentration produced a cataract within eight hours in the avian, it failed to produce any lens changes in the rabbit in eight hours, or at any period thereafter until the observations were discontinued after four weeks.

It is suggested that the failure to obtain cataracts in most mammals is due to a difference in metabolism as compared with the metabolism of avians, and not to a difference in the lenses themselves.

EXPERIMENTS ON LENS

The next obvious question is whether the action of dinitrophenol is an interference with the metabolism of the living lens or whether it also affects lens tissue *in vitro*. Lenses were removed from chickens, fat mice, and rabbits immediately after the animals had been killed. Removal was effected without injuring the lens capsule and the lenses were immediately immersed in solutions of buffered isotonic (1:1,000) dinitrophenol, unbuffered nonisotonic (1:1,000) dinitrophenol, and a control solution of the buffer material. In no instance could lens opacities be observed within two hours in the lenses from any of these species in any of these solutions. The examinations were performed by slitlamp microscopy in the same manner as in the living eyes as well as by other methods of magnification.

We must assume from the foregoing,

that dinitrophenol acts only on the living lens and does not produce cataract *in vitro* with comparable concentrations and in a comparable time.

SUMMARY

Dinitrophenol is estimated by Horner to be associated with the development of cataracts in obese humans in an incidence of 0.86-percent. It is associated with the development of cataracts in obese mice in an incidence of 7.5-percent. The cataract has often occurred in humans after the withdrawal of dinitrophenol therapy; it does not occur in obese mice after the withdrawal of dinitrophenol. It did not occur in ordinary nonobese mice under any circumstances.

Dinitrophenol causes lens opacities in fowl within eight hours after a diet containing dinitrophenol is started. The opacities clear spontaneously while the fowl are still on the diet. In comparable dosages, dinitrophenol failed to cause lens opacities in young or adult obese mice whether or not they were placed in higher temperatures.

The direct injection of dinitrophenol into the anterior chamber of chickens and rabbits causes lens opacities in each within approximately one-half hour. The opacities clear within 24 hours. Rabbits do not develop lens opacities when fed dinitrophenol.

The direct immersion of the lenses of chickens, obese mice, and rabbits in a solution of dinitrophenol does not cause an opacity in a comparable length of time.

CONCLUSIONS

The results of these experiments lead to the following conclusions and conjectures:

1. Dinitrophenol acts only on the lens *in vivo* of mammalian as well as avian species.

2. Lenses *in vitro* did not develop this opacity. This may be because: (a) dinitrophenol, when in the anterior chamber, forms another compound which then acts on the lens, or (b) the permeability of the lens capsule is different when the lens is *in vitro* as compared to its normal state, or (c) dinitrophenol interferes with some phase of metabolism of the living lens, such as causing an increased need for oxygen or producing more lactic acid.

3. The failure of mammals to develop the transient opacities observed in fowl is due to a difference in metabolism of the species; it is not due to a difference in the lenses themselves.

4. The variations due to metabolism are confirmed by the occasional occurrence of permanent cataracts in congenitally obese mice. Such opacities did not occur in nonobese mice. This frequency of cataract formation is comparable to the incidence of cataract in obese humans and may explain the previous failures

of numerous investigations to produce cataracts in experimental mammals.

5. The difference in incidence of cataracts in fowl and mammals is apparently not due to the difference in body temperature. The age of the animal is little, if at all, related.

Numerous questions related to dinitrophenol cataract remain unanswered. Is the cataract-producing action of dinitrophenol due to its effect on oxidation or on sugar metabolism or to something else? Why does the cataract which develops so rapidly in a chick clear spontaneously while the chick is still on the same concentration of dinitrophenol? Why did cataracts occur with great rapidity in human subjects months after the ingestion of dinitrophenol had been discontinued?

Work is being continued in an attempt to answer some of these vexing problems.

DISCUSSION

DR. CLYDE A. CLAPP (Baltimore, Maryland): As a member of the Commission, I should like to ask how many of the males developed dinitrophenol cataract. Are there any in the literature?

The second question is: What was the difference with the slitlamp in the so-called reversible opacities in the avians, and the permanent opacities that occurred in the mice?

DR. BETTMAN: There have been reports of dinitrophenol cataracts in human males in one or two instances. I have forgotten the precise number in the literature. It was not common, but it has been reported.

The slitlamp picture of the reversible cataracts in the chickens was a dense opacity entirely limited to the subcapsular layers of the lens. The remainder of the lens was not at any stage involved.

In the permanent opacities of the mice, the first observable change was the same type of subcapsular opacity, posterior at first, and then anterior; in association

with the development of the anterior opacity, or at about that stage, the nucleus begins to get a bit milky and then an opacity develops in the entire lens.

DR. CONRAD BERENS (New York, New York): I should like to ask one question. Are the terms "dinitrophenol" and "dinitrocresol" synonymous? A clinician in New York claimed a difference, but two obese women patients who were treated with dinitrocresol developed cataracts rapidly. One was 28 years old, and the other was 60 years old.

DR. BETTMAN (closing): The term "dinitrophenol" and the term "dinitrocresol" are not synonymous, but the drugs act, so far as we know, in precisely the same manner. Clinically, dinitrophenol has largely been used in the United States and dinitrocresol has been used largely in Europe. They both produce cataracts, and, as far as I know, they both act in the same manner. The group is usually called "dinitro bodies," because they are so similar in their action.

CATARACTA GLAUCOMATOSA ACUTA*

H. SAUL SUGAR, M.D.

Chicago

Since Vogt¹ first described the entity which he named "Cataracta disseminata subcapsularis glaucomatosa" or "Glaukomflecken" in 1930, only five reports of the condition have been made. No cases have been described in the English or American literature. For this reason, and because of the case with

Fig. 1 (Sugar). Diagrammatic drawing of cataracta glaucomatosa acuta (case 5).

which their presence may confuse the diagnosis of acute glaucoma during a congestive attack, six cases are herein reported.

This form of cataract consists of multiple, circumscribed, white spots of characteristic irregular form and radial arrangement lying beneath the anterior lens capsule. Their color varies from the bluish translucency of very thin lens opacities to a more porcelainlike whiteness. If seen during an acute glaucomatous attack,

the lesions are very white. When the intraocular pressure has been reduced, their color is much less intense, and their transparency is increased. The spots have been seen in only the anterior subcapsular cortex, never posteriorly. They do not extend beyond the pupillary zone. None has ever been described as occurring in the region of iridectomies. The axial area is always involved. Here the spots are rounded or dumbbell-shaped and often larger than elsewhere. More peripherally, they are elongated to follow the suture lines of the lens. At the pupil border where the lesions end, the spots are again often large (fig. 1). In general, they vary in size from 0.3 mm. to less than 0.02 mm. (Vogt).

These lens opacities do not change in size with the passage of time. However, since they decrease in intensity immediately after the acute episode with which they are associated, it is conceivable that the very faintest spots may disappear. Once the acute episode is entirely over, the spots do not change in size or color. They do not interfere with the shagreen of the lens. During and immediately after the acute episode, the lesions lie just underneath the capsular epithelium. Later, with the formation of new lens fibers, the spots are pushed deeper into the cortex. Vogt observed in one case that, after five years (from the age of 53 to 58 years), the opacities were 0.5 mm. within the lens cortex. In two cases seen by me at about the time of the acute episode and again after eight years and six years, respectively, the spots occupied a level within the lens cortex equivalent to two thirds of the thickness of the cornea.

There is no significant visual impair-

* From the Illinois Eye and Ear Infirmary and the Department of Ophthalmology, University of Illinois. Under a grant from the W. K. Kellogg Foundation.

ment due to the presence of these thin lens opacities.

The occurrence of lens opacities which Vogt described in his original report was associated only with acute glaucoma. However, since that time, he² observed similar opacities in a patient after a severe contusion of the bulb. Similar cases have since been observed by Bücklers (1934),³ Van Lint (1937),⁴ and Sommer (1940).⁵ In each of these cases, however, there was evidently a momentary severe ocular hypertension, so that the term "Cataracta glaucomatosa acuta" may still be applied to them. Actually, both types are forms of traumatic cataract. The use of the designation "glaucomatosa acuta" is important to distinguish the entity herein described from other forms of cataract in glaucomatous individuals. Seidenari⁶ has included both types in the term "Cataracta glaucomatosa."

The relation between the lens opacities and the acute episode is evident from the fact that the lesions lie directly subcapsularly immediately after the episode. In a case of Kovarskaya and Krolh,⁷ the lens was found to be entirely normal when seen two days before an attack of acute glaucoma, following which the opacities were found. Vogt found 14 instances of these opacities among 74 patients with acute glaucoma which were seen by him between 1930 and 1937.

Vogt believed the lens opacities to be due to exudation. My own view is that the lesions are due to traumatic dissolution of the most delicate terminal portion of the lens fibers at the suture areas, in the uncushioned pupillary area of the anterior cortex. This would account for the radial arrangement of the opacities. The edema present during the acute attack would account for the more intense whiteness during that time.

The diagnosis depends on accurate biomicroscopy with the slitlamp and micro-

scope. Correct diagnosis has importance during an acute glaucomatous attack, since the opacities may be mistaken for exudate on the anterior capsule in the presence of marked corneal edema. This occurred in one of my cases. In two others, a diagnosis of capsular exfoliation

Fig. 2 (Sugar). Stereophotograph of subcapsular opacities in an eye that had suffered an attack of acute glaucoma.

had previously been made. All three of these patients were seen by me within a period of three weeks.*

Recognition of "Glaukomflecken" may also aid in establishing a definite diagnosis of previous acute glaucoma in an eye in which an acute attack has been completely relieved, as occurred in a case described by Weill and Hordman.⁸ It would be possible also to recognize two or more previous attacks in the same eye, if the attacks were severe enough to cause the lens lesions, and if a sufficient time interval were to elapse between the separate attacks for new, clear, lens fibers to form.

CASE REPORTS

Case 1. A. K., a 50-year-old woman, was first seen by me in February, 1938. She stated that for a period of several months redness and aching of the right eye recurred in the late afternoon and after reading or seeing motion pictures.

* Since writing this paper, two additional cases of "Glaukomflecken" have been observed, one after an interval of five years following an acute glaucomatous attack; the second, a recent case which had previously been considered to be glaucoma capsulare.

One week before admission to the Illinois Eye and Ear Infirmary (February 21, 1938), the right eye had become red and painful and remained so. On admission, the visual acuity of the right eye was reduced to perception of hand movements; that of the left eye was normal. Tonometric readings were: R.E., 60 mm. Hg (Schiotz); L. E., 19 mm. In spite of the intensive use of eserine, the intraocular pressure in the right eye could not be reduced satisfactorily. On February 25, 1938, an iridectomy was, therefore, performed. The tonometric readings thereafter always remained normal. The patient was followed by me for a period of three years and then again examined in April, 1946. Definite "Glaukomflecken" were present in the anterior cortex at a depth equal to about two thirds of the corneal thickness.

Case 2. J. K., a man, aged 44 years, was first seen by me in December, 1940. He had experienced severe pain in the right eye for the past five days. Treatment with miotics had been started on the third day but was ineffective. On admission to the Illinois Eye and Ear Infirmary (December 23, 1940), the tonometric reading for the right eye was 80 mm. Treatment with miotics continued to be ineffective. An iridectomy *ab externo* with incarceration of the iris was performed on the day following admission. The intraocular pressure remained normal thereafter. The patient was seen again in April, 1946, at which time typical "Glaukomflecken" were present in the anterior cortex at a depth equal to about two thirds of the corneal thickness.

These first two cases are cited to show the typical change in relative position of the lens opacities as time passes. In both of these cases, the depth of the opacities was approximately the same, equivalent to two thirds of the thickness of the corneal stroma near its apex.

Case 3. J. K., a woman, aged 50 years, was first seen at the Illinois Eye and Ear Infirmary on January 28, 1946. She complained of having had pain and redness of the right eye and severe supraorbital and temporal headache for the past three weeks, following a severe episode of influenza. The cornea of the right eye was steamy, the pupil dilated to 7 mm., and the tonometric reading was 57 mm. Hg (Schiotz). After clearing of the cornea with glycerin, the anterior chamber was found to be very shallow. The aqueous was clear. Opacities in the region of the anterior capsule were interpreted to be capsular exfoliation. Some excavation at the upper temporal border of the disc was believed to be present. The left eye showed no evidence of capsular exfoliation nor lens opacities.

The patient was treated intensively with eserine without effect. An iridencleisis was successfully performed on January 30, 1946, at the Chicago State Hospital, where the patient was being treated for involutional melancholia. She was first seen by me two weeks later, at which time the right lens opacities were found to be typical cataracta glaucomatosa acuta.

Case 4. Mrs. E. S., aged 65 years, was first seen by me on February 28, 1946. Four weeks previously she had experienced slight attacks of blurred vision with slight aching around the left eye. One week later, a severe attack occurred and persisted. The right eye had been enucleated following similar attacks of blurred vision and subsequent antiglaucoma surgery. Vision in the left eye was 20/200, with and without correction. A caput-medusa type of conjunctival injection was present. The pupil was dilated and the anterior chamber was found to be shallow. "Glaukomflecken" were present. They had been interpreted as capsular exfoliation. The disc was normal. The

tonometric reading was 60 mm. Hg (Schiøtz). Intensive treatment with eserine was ineffective, so an iridectomy-iridencleisis was performed. The opacities on subsequent examinations showed less intense color but did not change significantly otherwise.

Cases 3 and 4 are interesting in that both had been previously diagnosed as capsular exfoliation. During the acute attack, the subcapsular position is, of course, difficult to ascertain, but the presence of changes in the center of the pupillary area is a pathognomonic sign of cataracta glaucomatosa acuta in contradistinction to capsular exfoliation.

Case 5. Mrs. A. H. M., aged 49 years, was first seen by me on February 22, 1946. Three weeks earlier, while vacationing in another state, she had awakened with severe headache. She was treated for nearly three weeks with atropine and penicillin. During the past three days, she had received eserine instead. Examination revealed a reduction of visual acuity in the left eye to perception of hand movements at 1 foot. The cornea was markedly steamy. Glycerin dehydration was ineffective in clearing the cornea. Pigment deposits were visible on the posterior corneal surface. The anterior chamber was only slightly shallow. Whitish spots appeared to be present on the lens capsule. In view of the history, I interpreted the hazy spots to be exudate. The tonometric reading with the Gradle-Schiøtz tonometer was 60 mm. Hg. Intensive treatment with eserine was instituted but was ineffective in reducing the intraocular pressure. An iridectomy-iridencleisis was done on February 22, 1946. Since then, the vision has returned to 20/25 with correction, and the tension has remained normal. The first post-operative examination revealed that the capsular spots were typical subepithelial lens opacities (fig. 1) of cataracta glau-

comatosa acuta. These were less intense in color than during the acute attack. No evidence of primary uveitis was present.

Case 5 is an example of a mistake in diagnosis resulting from the presence of "Glaukomflecken." In this instance, the first oculist who saw this patient probably used atropine as a result of making the same mistake. Fortunately, the history of ineffective use of atropine for a relatively long period pointed out the correct treatment.

Case 6. Mrs. J. P., aged 59 years, was examined by Dr. S. J. Meyer on June 9, 1941. She was found to be 3.75 diopters hyperopic in each eye. Tonometric readings were: R.E., 24 mm.; L.E., 17 mm. Hg (Gradle-Schiøtz). An hour after instillation of euphthalmine for retinoscopy, the readings were: R.E., 22 mm.; L.E., 20 mm. No lens opacities were present. On April 10, 1946, she was seen by Dr. Meyer and me. She had had no ocular difficulty until 12 days previously, when she began to have headaches on the left side. Vision of the left eye was blurred. On the following day an antiglaucoma iridectomy was performed for acute glaucoma.

Upon examination, on April 10, 1946, large typical "Glaukomflecken" were found under the left anterior capsule. The tonometric reading in this eye was 22 mm. Hg (Gradle-Schiøtz).

Case 6 differs from the other three recent cases described in that the patient had symptoms only one day before surgical intervention. In the other three, the attack had lasted three or four weeks before intervention. It is, therefore, unlikely that a long period is required to produce the lens opacities. In many other cases of acute glaucoma with high tension, even those untreated for several weeks, no "Glaukomflecken" have been seen. The histories in the cases of traumatic "Glaukomflecken" indicate that a momentary

very high increase of intraocular pressure may be all that is required for their development.

In this case, the previous examination in 1941 revealed no pathologic condition of the lens, thereby indicating the relation between the acute episode and the presence of the lens changes.

CONCLUSIONS

Six cases of cataracta glaucomatosa acuta are reported together with a summary of the literature. The condition is important chiefly in differential diagnosis and in establishing the diagnosis of a previous attack of acute glaucoma.

DETERMINATION OF OCULAR TENSION AND RIGIDITY IN RABBITS*

ERNST SCHMERL, M.D.,[†] AND BERNHARD STEINBERG, M.D.
Toledo, Ohio

Because of the insufficient data in the literature on the subject of this communication, it was deemed necessary to evaluate the normal range of ocular tension and rigidity in rabbits under varying physiologic conditions prior to experiments on changes of ocular pressure and tension.

There are two accepted methods of determining intraocular pressure; namely, the manometric and the tonometric. For purposes of comparative studies over a long period, the tonometric method was considered preferable.

METHODS AND MATERIALS

Twenty rabbits of both sexes of New Zealand and Checkered Giant varieties, varying in age from one to two years, were used. Ocular tension and rigidity were ascertained by a Schiøtz tonometer which had been standardized at the New York checking station. The third corrected curve of Schiøtz was used.

The eye was anesthetized with one drop of 1-percent butyn. To ascertain ocular rigidity, tension was obtained with two weights, the 5.5-gram and the 10-gram. Whenever two readings with the two weights did not reveal significant differences, the rigidity was assumed to be normal. A higher tension with the 10-gram than with the 5.5-gram weight indicated an increase in rigidity; a lower tension, a decrease.

* From Toledo Hospital Institute of Medical Research. This work was supported by a grant from the Snyder Ophthalmic Foundation.

[†] Research Ophthalmologist of the Snyder Ophthalmic Foundation.

During the first phase of the experiments, the normal values were determined over a period of three weeks. The second phase of the experiment consisted in instilling into the eyes a solution of 1-percent paredrine, 1-percent pilocarpine, and 1-percent atropine. The drugs were introduced in single drops three times over a 15-minute period. The readings were made in 30 minutes and in four hours.

The third phase of the experiment consisted in the determination of ocular tension and rigidity by hypotonic (distilled water), hypertonic (4-percent saline), and isotonic (0.9-percent saline) solutions. These solutions were given by stomach tube in 40-c.c. volumes per kilogram of body weight. Readings were made over a period of four hours at 5- to 10-minute intervals.

Averages and standard deviations were evaluated in all experiments. Application of the following formula determined whether the findings obtained in the various experiments were significant. Differences were considered significant when they were larger than $3\sqrt{SE_{MX}^2 + SE_{MY}^2}$.

SE—standard error of the distribution of the magnitudes.

M—arithmetic mean.

x—varying abscissal value.

y—varying ordinate value.

the 10-gram weight, the tension was from 20 to 34 mm. with a standard deviation of 2.5 to 6 (table 1). There was no essential difference in the tensions between morning and afternoon determinations. It was noted that the more excitable rabbits were prone to greater variations in tension. There were no significant differences in the results for the two different weights (table 2).

Instillation of 3 drops of 1-percent paredrine in the eyes of eight animals showed an ocular tension varying from 24 to 36 mm. with the 5.5-gram weight and 24 to 38 mm. with the 10-gram weight. Although the average readings appear higher than without paredrine, the majority of animals showed no significant changes either in tension or in rigidity. Introduction of pilocarpine and atropine was equally without appreciable changes (table 3).

Oral administration of isotonic, hypotonic, and hypertonic solutions showed significant changes. Following the use of hypotonic solutions, there was an increase in tension in 10 to 15 minutes. The rigidity remained unchanged. The difference in tension from the normal values varied from 6 to 14 mm. Hg. Isotonic solutions induced no significant changes. Administration of hypertonic solution resulted in a decrease of tension but without change in rigidity. The decrease occurred within 15 minutes and was less than normal by 6 to 10 mm. Hg (table 4).

DISCUSSION

The choice of method of estimating ocular tension in experimental animals depends on the purpose of the investigation. The manometric procedure produces variable degrees of trauma which may influence the experiment, and the number of determinations is necessarily limited. The advantage lies in obtaining absolute values. The tonometric method, on the

other hand, allows repeated determinations without inflicting injury. It must be emphasized that the method measures the impressibility of the wall of the eye from which tension is deduced. If comparative values are desired to determine experimental changes, the tonometric procedure is adequate. However, the standard deviation should be ascertained to avoid ascribing undue significance to all variations. To obtain comparative values, a sufficiently large number of determinations must be made, the averages determined, and standard deviations calculated.

Gruenhagen's¹ manometric determinations of the rabbit's ocular tension varied between 25 to 26.5 mm. Hg. The range of tonometric readings in our experiment was from 20 to 30 mm. These readings also agree with results obtained in man.^{2, 3, 4} In the normal human eye, there

is a diurnal variation,^{5, 6} frequently of 5 to 6 mm. Hg. The tension is greatest in the morning and falls gradually during the day. It begins to rise again at night. It was noted that the difference in the morning and afternoon tension in the rabbit was not significant.

In evaluating the findings in these experiments, the results of Friedenwald's tonometric studies⁷ were employed. Two different weights were used. When similar readings were obtained with the two weights, the rigidity was considered normal. Friedenwald's definition of the term, rigidity, is the resistance which the eye exerts to distending forces.

The action of atropine and eserine on ocular tension has been ascertained by other investigators.⁸ Their results indicated that by the use of manometric methods there were no significant changes. Slight deviations found by other workers⁹

Chart 1 (Schmerl and Steinberg). Examples of changes in ocular tension of the left eye of a rabbit before and after oral administration of isotonic, hypotonic, and hypertonic solutions.

may be accounted for by conditions in the experimental procedures, such as partly filled anterior chambers.

Drinking of water tends to raise the ocular tension, and the Marx test is an application of the phenomenon. Studies utilizing the "drinking test" indicated that relatively small volumes of water are capable of increasing the tension in the normal eye¹⁰ and the more so in the glaucomatous.¹¹ On the basis of such experiments, it was postulated that osmotic pressure does not play a part in the elevation of the ocular tension. It was also pointed out^{12, 13} that after introduction of hypertonic salt solution, the blood volume tends to return to normal within 30 minutes, whereas the ocular tension remains decreased for several hours. The physicochemical reactions involved in this process are not clearly understood.

In the experiments reported here, it is apparent that a certain relationship exists between salt concentration and ocular tension. With ingestion of hypotonic solutions, the tension is increased; with hypertonic, it is decreased; and with isotonic, there are no significant changes.

SUMMARY

Tonometric determinations of the impressibility of the wall of eyes were made in a number of rabbits over a prolonged period. The tension and the rigidity were then deduced. Determinations were made at different periods of the day, after instillation of paredrine, atropine, and pilocarpine, and after ingestion of isotonic, hypotonic, and hypertonic salt solutions. Average values, standard deviations, and significant differences were determined.

THE AUTONOMIC NERVOUS SYSTEM IN OCULAR DISEASES*

DAVID O. HARRINGTON, M.D.
San Francisco, California

It is the purpose of this thesis to present certain clinically studied ocular disturbances both functional and organic, which have as their common etiology dysfunction of the autonomic nervous system.

Recent knowledge of the role played by the autonomic nervous system in the functioning of the body has opened new vistas. The mechanisms are known by which pain, cold, emotional states, and other conditions that excite autonomic discharges can induce or participate in pathologic processes. Morbid phenomena which have long been inexplicable are thereby reasonably explained.

The borderline between normal and abnormal physiology and between functional and organic diseases is nowhere so thin as in the effects produced by dysfunction of the autonomic nervous system.

Those champions of the modern concept "Psycho-somatic medicine," such as Dunbar,^{1, 2} and Weiss and English,³ have found their best and most readily provable arguments in the study of the organic pathology resulting from autonomic imbalance. Actual structural change in the cells consistent with organic disease processes will be seen to follow prolonged physiologic upsets.

Subjective symptoms of functional origin are found giving rise to the objective signs of disease.

There are, perhaps, few places in the body so well adapted to the clinical study

of such phenomena as the eye, much of whose normal physiology is under autonomic control.

ANATOMY

In the history of the investigation of the vegetative nervous system, anatomic knowledge developed far ahead of physiologic experiment.

Relatively little still is known of the central connections of the sympathetic-nervous-system fibers in the brain. On the basis of clinical and experimental studies, however, it is conjectured that such centers probably exist in the cerebrum, the hypothalamus, the medulla, and the cord (Beattie *et al.*,⁴ 1930).

Evidence of cerebral control (especially the frontal lobes) over the sympathetic fibers of the eye is slight, but stimulation of a center immediately lateral to the infundibulum in the hypothalamic region brings about a pupillary dilatation, separation of the lids, and retraction of the nictitating membrane (Beattie,⁵ 1935). This effect persists after section of nerves II, III, and V, but is stopped by destruction of the sympathetic. The general vasomotor centers are situated in the medulla. An "inferior ciliospinal center" for sympathetic control of the eye undoubtedly exists in the upper part of the cord between the levels of VI C and IV T.

Arising in the intermedio-lateral tract of the gray matter of the ciliospinal center, the preganglionic sympathetic fibers leave the central nervous system by the ventral roots of the thoracic nerves I, II, and III, with the larger number of fibers to the eye in the first thoracic root. The white rami communicantes continue the

* From the Department of Surgery, Division of Ophthalmology, University of California Medical School. Presented as a candidate's thesis for membership in the American Ophthalmological Society, November, 1945.

course of these fibers up the cervical-sympathetic chain, through the inferior and middle cervical ganglion to their termination in the superior cervical ganglion.

The majority of the nonmedulated, postganglionic fibers leave the superior cervical ganglion as the nervous caroticus internus, which accompanies the carotid artery through the carotid canal into the skull, where it breaks up into a fine plexus adherent to the vessel wall. This is divided into the internal carotid plexus and the cavernous plexus.

From the cavernous plexus, branches are given off to the third nerve, to the fourth nerve, to the Gasserian ganglion, and the first division of the fifth nerve, and thence to the eye by way of the long ciliary nerves, to the ciliary ganglion, and thence to the eye as vasomotor fibers via the short ciliary nerves.

From the carotid plexus branches are given off to the sixth nerve, to the branches of the ophthalmic artery, and to the periorbita, the muscle of Müller, and possibly the lacrimal gland.

The parasympathetic nervous system of the eye is found in association with the third nerve, in which are found the pupillo-constrictor fibers to the iris and the nerves to the ciliary muscle, relayed to their end stations by way of the short ciliary nerves (Duke-Elder⁶).

For a comprehensive review of the autonomic innervation of the eye, reference is made to Kuntz⁷ and White and Smithwick.⁸

PHYSIOLOGY

For our purposes, a consideration of the physiology of the autonomic nervous system will be limited to a brief review of its ocular relationships with particular emphasis on vasomotor control in the eye.

A great part of the work which has led

to our present understanding of the physiology of the sympathetic nervous system has been carried out by Cannon⁹ and summed up in his book, "The Wisdom of the Body." He particularly emphasized the essential character of the system in conditions of stress and strain. This applies to the eye no less than it does to other parts of the body. Some of the more common conditions which arouse its activity are pain, extremes of temperature, lack of oxygen, infection, and intense emotional or psychic trauma. He has stated that this mechanism may actually be harmful unless the emotion is transformed into action. "If no action succeeds the excitement and the emotional stress (even worry or anxiety) persists, then the bodily changes due to the stress may be profoundly upsetting to the organism as a whole" (Cannon,¹⁰ 1933). This same point has been expressed by Fulton¹¹ in the statement that "the heart and circulation may be worked just as hard from an armchair as from a rower's seat."

Just as anatomic investigation has demonstrated the importance of the hypothalamic region in the autonomic nervous system, so physiologic experimentation has shown that the hypothalamus, in addition to carrying out the autonomic expression of emotion, serves as a regulator of body temperature, through vasomotor control, and the whole delicate involuntary adjustment to the external environment. Alvarez¹² has presented convincing evidence that the hypothalamus can be upset by fatigue, lack of sleep, and nervous strain, and that, in many persons, it behaves erratically because of poor nervous inheritance.

Of all functions of the autonomic nervous system, that of the vasoconstrictor action of the sympathetic is of most interest to the ophthalmologist. In addition to distributing vasoconstrictor fibers to

the entire surface of the body, the sympathetic system constricts the cerebral and retinal arterioles (Penfield,¹³ 1932).

While the most active vasoconstrictor action supposedly takes place in the arterioles, a definite nervous control of the capillaries and veins has also been demonstrated. Cessation of blood flow through a capillary loop results from constriction of the Rouget cells and swelling of the endothelial-cell nuclei and follows a stimulus with too short a latent period to be anything but nervous action. Nervous control of the veins has also been demonstrated, and there is good reason to believe that the engorgement of the veins after sympathectomy is due to their release from the vasoconstrictor center.

Because the control of the entire circulation is essentially directed to regulate the blood supply to the capillaries, they are the vital part of the circulation. This is especially true of the eye and most particularly true of the macular area of the retina, whose metabolic interchange is wholly through the underlying choriocapillaris.

The contractility of the arterioles, capillaries, and venules of the eye, as elsewhere in the body, is controlled by two mechanisms, a nervous and a chemical, by the reciprocal action of which the small vessels are constantly kept in a state of tonicity. Reference has been made to the physiology of nervous control. Chemical control is maintained more directly by local conditions and forms a fine adjustment of great precision, though there is a close interrelation between the two.

The chemical control of the circulation is carried out by two groups of substances: the first, hormonal and acting as constrictors and typified by pituitrin and adrenalin; and the second, produced locally by the tissue cells and typified in histamine. The complete reaction pro-

duced by these histamine-like substances is a "triple response," consisting of a primary and local dilatation of the minute vessels, a local increase in capillary permeability, and a widespread dilatation of neighboring arterioles. The occurrence of this reaction in the vascular system of the inner eye will be shown to be of considerable importance. Recent experiments by Shorr *et al.*¹⁴ have demonstrated the production by the kidney of a vaso-excitor material, probably identical with the renin-angiotonin system in its action on the terminal vascular bed, and an opposite-acting, vaso-depressor material produced by the liver and skeletal muscle whose genesis is anoxia in tissues.

METHOD OF STUDY

The various clinical methods of study of vasomotor pathways and reactions have been well described by White and Smithwick⁸ and Kuntz.⁷ Reference is made primarily to peripheral vascular disturbances in the extremities, but the methods used are equally applicable to the study of ocular vasomotor disturbances. These methods have been augmented by observation on certain objective and subjective ocular signs and symptoms indicative of autonomic imbalance and their relationship to the clinical entity of "vasoneurotic diathesis" described by Horniker¹⁵ and by Gifford and Marquardt.¹⁶

Due to lack of facilities, complete studies were carried out on relatively few of the cases presented in this paper. However, it became possible through observation of these cases to recognize a symptom complex in the others, which, when associated with certain typical signs of vasomotor instability, was sufficiently characteristic almost to preclude the necessity of pressor tests, skin-temperature readings, capillary microscopy, diagnostic procaine block, and foreign protein test.

THE AUTONOMICALLY UNSTABLE PERSON

The complete picture of the "typical" autonomically unstable individual, as seen in great numbers in the military forces of the United States, is as follows: An asthenic young man, about 22 years of age, rather nervous and ill at ease during questioning and examination, with from 9 to 18 months' training and about 7 months of overseas duty or at some rather isolated mainland post. He complains of frequent or constant headache, usually unilateral and frequently retrobulbar in location. He often has transient dizziness or syncope associated with blurring of vision which may last from a few seconds to 10 minutes. The visual disturbance varies from a slight "film" to complete "blackout." The patient states that he has lost some weight, often as much as 20 pounds; that he has always been "nervous" but that in recent months he has become more so and he has had insomnia. He sometimes volunteers the information that he thinks this nervousness is due to "too much smoking" or vice versa, that he is smoking much more lately because of his nervousness. In any case, he has often doubled his cigarette consumption. If he has been in active combat, he readily admits to being very anxious and emotionally upset immediately preceding, sometimes during, and after action. If he is married, which is usually the case, he confesses anxieties about his wife, his children, his farm crops, or his domestic problems in general. Nostalgia is a frequent complaint.

When questioned about his family, there is frequently a history of an ailing mother with "sick headaches." There is usually a fairly stable family background with little abnormal parental behavior.

Physical examinations (aside from the various ocular signs to be described later) shows a rather tall, thin, under

weight young man. Hands and feet are moist to actually wet with perspiration regardless of the climatic conditions prevailing at the moment of examination. (Some men were examined in the northwestern United States in winter and others in the tropics with high temperatures and humidity.) The fingers and toes are cold to touch. The finger tips become quickly more cyanotic than normal, when held hanging at the sides, and very pale when elevated for a few minutes above the head. The pupils are dilated in an ordinarily light room but respond readily to light and accommodation. The blood pressure is an average 120/70 and is affected very little if at all by pressor test. The pulse is inclined to be more rapid than normal in a resting person. General physical examination, including a thorough search for any possible foci of infection, is negative except for the occasional finding of a granuloma at the apex of a devitalized tooth and occasional hypertrophied tonsils.

There is a fine tremor of the extended hands, at times very marked. Psychiatric evaluation, which was obtained in a fairly large number of cases, revealed tendencies toward, or frank and outspoken anxiety neurosis. Several soldiers showed many of the signs and symptoms of "combat fatigue," and in a few instances, the autonomic instability was so marked as to make the diagnosis of true "combat fatigue" open to question.

The military duty to which these men were subjected varied tremendously. Some had had most difficult and prolonged combat duty with days and weeks of exposure to battle conditions. They had lived in muddy fox holes in temperatures well over 100°F., with humidity of 80 to 90 percent. Food had been mostly C and K rations. Sleep was fitful because of constant alerts. They had endured in-

cessant bombing and heavy shell fire and, although they had suffered no physical injury of any consequence, had been subjected to intense psychic trauma. Others had had prolonged periods of

time. There were numerous instances in which the only rigors of military duty were those found in "boot camp" or indoctrination schools and training centers. For the most part, these men were very young,

duty in isolated outposts such as the Aleutian Islands, where their chief enemy was lack of activity and exquisite boredom. They were repeatedly exposed to subzero weather and, in several instances, suffered greatly from it. Some had suffered from intense glare of the tropic sun on water and attributed their ocular disturbances to this glare, whereas others, including several submariners, were denied the sight of the sun for weeks at a

were frankly, miserably homesick. Their psychiatric examinations showed almost uniform tendencies toward true anxiety neuroses.

It will be seen from analysis of the foregoing data that all of these patients had two things in common: They demonstrated the clinical picture of vasoneurotic diathesis, and they were all subjected to one or more known autonomic nervous-system stimulants; namely, emotional or

psychic trauma, exposure to extremes of temperature, the vasospastic action of cigarettes, occasional infection, pain, dehydration and hypoglycemia induced by prolonged periods of strenuous muscular exertion, and fatigue approaching exhaustion.

Certain other cases will be discussed in which it was felt that the ocular disturbances were the result of direct trauma to the eye, as in contusion or exposure to infrared or heat rays, both of which are known to give rise to histamine production with the resulting "triple response" in the tissues involved.

OCULAR MANIFESTATIONS

The ocular manifestations of autonomic-nervous-system dysfunction to be considered are as follows: (1) central angiospastic retinopathy; (2) ocular changes in Raynaud's disease; (3) amaurosis fugax; and (4) commotio retinae.

CENTRAL ANGIOSPASTIC RETINOPATHY

This is the term applied by Gifford and Marquardt¹⁶ to a type of macular retinal lesion which they felt to be definitely of circulatory origin and of sufficient importance to be considered a clinical entity.

It is my opinion that their conclusions and the name were well supported by their case reports. My own case reports will be seen to confirm their findings in many respects. As pointed out in their article, the identical clinical picture has been described at intervals in the literature under the names: recurrent central retinitis; retinitis centralis; central serous retinopathy; preretinal edema; idiopathic flat detachment of the retina; retinitis centralis annularis; central angiospastic retinitis; angiosclerotic and angiospastic retinoses; juvenile exudative macular retinitis; and choroiditis centralis serosa.

In the majority of reports, small groups of cases were seen and, for the most part, the investigators considered the condition of inflammatory origin. A notable exception to this was the suggestion of Kraupa¹⁷ that the lesions could be attributed to retinal ischemia resulting from capillary changes. It remained for Horniker,¹⁵ and later for Bailliart,¹⁸ and Gifford and Marquardt¹⁶ to establish evidence of vasomotor instability in these cases and to demonstrate the vasospastic etiology of the retinal lesion.

Shortly after the entrance of the United States into World War II, medical officers in the United States Navy began to see cases of binocular or monocular macular lesions in young people, in numbers out of all proportion to those seen in civilian practice in the same age group. The cases appeared with such regularity, and so many widely scattered officers commented upon them, that a study of the condition was requested by the National Research Council, Subcommittee of Ophthalmology, and was undertaken by Dr. F. C. Cordes.¹⁹

His preliminary report was based upon data furnished by 11 Naval medical officers stationed in Pacific Naval hospitals, supplemented by personal observations of a few cases. Data on approximately 16 cases for this report were submitted by me, and I was in frequent communication with Cordes during its preparation.

From a close study of my own cases and of the description of the cases submitted by the other medical officers and by Cordes, it is obvious that all were concerned with the same clinical entity. Furthermore, these cases fit perfectly the description which Horniker, and Gifford and Marquardt give of the lesion which they call "central angiospastic retinopathy," and which Duke-Elder²⁰ calls

11	O.D.	None	Fine pigment	Absent	Small, sharp edges
12	O.U.	Gray elevation, halo	Coarse mottling	Absent	None
13	O.U.	Marked gray edema	Fine granular	Absent	Small, red, sharp
14	O.D.	Blurred gray macula	Suggestion, fine white dots	Absent	None
15	O.U.	None	Faint, pigment change	Absent	None
16	O.D.	None	Coarse granular, marked	Absent	Sharp, small, red
17	O.U.	Marked, bright halo	Coarse granular	Absent	None
18	O.S.	Slight, early	Fine granular	Absent	Hole $\frac{1}{4}$ disc diameter
19	O.U.	None	Coarse, 5-6 yellow dots	Present	None
20	O.S.	None	Faint, fine pigment	Present	Minute, vertical oval
21	O.D.	Early edema, ring reflex	Granular with yellow dots	Absent	None
22	O.D.	Slight	Fine granular	Absent	Minute red hole
23	O.D.	Early slight edema	Coarse, mottled	Absent	Small, dark red hole
24	O.U.	Blurred, gray maculae	Fine, numerous yellow dots	Absent	None
25	O.D.	Slight grayness	Coarse, granular	Absent	Minute red, oval hole
26	O.D.	None	Fine	Absent	Minute red hole
27	O.S.	None	Slight	Absent	Minute, sharp hole
28	O.U.	Gray elevation macula	Fine	Absent	Small, sharp edges
29	O.D.	None	Heavy, coarse	Absent	Dark, sharp edges
30	O.D.	Slight	Coarse, granular	Absent	Small, oval, red
31	O.U.	Marked in early stages	Heavy, with yellow dots	Absent	Small mound with crater
32	O.U.	None	Faint	Absent	Small, sharp, round
33	O.U.	Marked in early stages	Early, moderate	Absent	Extremely small
34	O.U.	Slight	Coarse, granular	Absent	Irregular, small, right
35	O.D.	Gray, bright halo reflex	Fine, many yellow dots	Absent	Minute, oval, red
36	O.U.	Marked in early stages	Pear shaped, heavy	Absent	Mound with crater
37	O.U.	None	Moderate, some white dots	Absent	Round, sharp, red
38	O.D.	Slight	Many yellow dots	Absent	Small, crater like
39	O.U.	Slight	Coarse, many yellow dots	Absent	None
40	O.U.	Gray, small in area	Coarse, marked	Absent	Very small

"central serous retinopathy" in his textbook discussion of macular capillary disturbance.

For purposes of clarity and simplification, one case only will be reported in detail with results of examination of the peripheral vascular and autonomic nervous systems. The remaining 39 cases will be reported in tabular form. It is unfortunate that in this investigation facilities were not at hand with which accurate measurement could be made of skin-tem-

perature changes; but, in the majority of instances, the changes were so marked as to be readily measured with relatively crude methods and, as mentioned above, the clinical manifestations were so marked in many instances as almost to preclude the necessity of special vasomotor tests.

CASE REPORT

J. D. S., a corporal, U. S. Marine Corps Reserve, aged 22 years, entered

the hospital on November 29, 1944, with a diagnosis of amblyopia. His trouble began in early June, 1944, while aboard a ship approaching Saipan, preparatory to invasion. He first noticed a very severe, constant "boring" type of right-sided headache which centered mostly in the right orbit and was not relieved by sleep or aspirin. A short time later he noticed a blurring of vision which at first occurred in "waves" and would then clear. This rapidly became more constant until vision was very poor most of the time. He stated that he was extremely nervous but "no more frightened than the rest of the fellows—which was plenty." During the long sea voyage, he had increased his cigarette consumption from 15 to 45 or 50 a day—mostly "because of nervousness and nothing to do." He also noticed marked photophobia but considered this natural from the glare on the water.

During the amphibious attack on the island, he was in one of the first "waves" ashore and was subjected to vigorous shell and small-arms fire and some very near misses and sharp blast concussions. His head continued to ache but was much worse during any lull in his activity. In the course of the next week, he was under almost continuous and very severe nervous tension, with little sleep or rest. Vision became so blurred in his right eye that he began shooting from his left shoulder, although at times there was noticeable blurring of the vision of the left eye.

He volunteered the information that for the past seven or eight years he had "never been able to depend on his right eye, which frequently blurred out, especially when he was under nervous tension or when it was very cold." For this reason, he did not report to sick bay, believing that the disturbance was temporary as it had been before. His home was

in Wisconsin, and he had frequently noticed that he suffered more from the winter cold than most of his friends. He could not wear gloves because his hands "always got wet with sweat and then would freeze."

He carried on as best he could through the remainder of the invasion, reporting to the doctor because of his headache and poor vision only after his sector had been declared secure. Examination at that time showed vision to be 2/20 in the right eye, and a note was made in the health record that the "fundus details were indistinct and the retina seemed edematous." He was evacuated to a base hospital.

General physical examination showed a husky, well-developed young man who appeared well controlled and was very coöperative. There were no abnormalities in the system, and a thorough search for foci of infection including teeth, nose, and throat, and prostate were normal. X-ray studies of the chest were normal. Intradermal tuberculin test in 1:10,000 dilution was negative. Sedimentation rate was normal. Blood Kahn test was negative.

Patent clinical evidence of vasoneurotic diathesis was manifest as follows:

1. The pupils measured 8 mm. in diameter as compared with 2 and 3 mm. in two other enlisted men under the same lighting conditions.

2. The palms of the hands were grossly wet, so that, if a ruler edge were passed across them lightly, a pool of water collected in the center. This was in marked contrast with two normal control subjects.

3. Elevation of the hands above the head for three minutes produced a marked blanching of the fingers. When the hands were returned to shoulder level, they quickly showed a very blotchy appearance. This was noticed to a very mild degree in the controls.

4. With the hands hung dependent for three minutes, there was a noticeable cyanosis as compared with the controls.

5. The hands were cold to touch, especially the finger tips as compared to the controls'.

6. There was a considerable fine tremor of the extended hands.

7. The patient appeared calm but, when questioned about the tremor, stated that he always had it when he was "very nervous like I am now."

8. During the course of a rather short examination, the axillary perspiration soaked through and stained a large area of the shirt in marked contrast to the controls and the examiner in the same room.

Ocular examination. Vision in the right eye was 20/200 (2/20); left eye 20/20.

Visual field taken on the tangent screen at 2 M. with 2-mm. test object showed a 2° central scotoma, sharp in outline and dense, with the bulk of the defect extending below and nasal to fixation.

A test for metamorphopsia suggested by Comdr. Frank P. Smart²¹ was positive to a marked degree in the right eye and suggestive, although not definite, in the left eye. The test consisted of having the patient fixate steadily a cross placed on the middle line of a music staff of five lines. He then drew the lines as he saw them. The two outer lines of the staff appeared to be bent outward from the fixation point, indicating an inward traction of the nerve elements of the macular area. This type of metamorphopsia was a very constant finding in most of the cases tested.

External examination of the eyes including cornea, iris, and lens was negative. The vitreous was clear. The macular area of the right eye showed a pear-shaped, granular, and pigmented lesion, with sharp edges approximately the diameter of two retinal-vein trunks.

Around this the retina had a grayish tinge and showed a few faint radiating striations. There were five or six small yellowish dots in the area. The foveal reflex was absent. When the ophthalmoscope beam was cut down to a narrow slit, the central lesion appeared to be definitely depressed, and the surrounding retina slightly elevated, giving the appearance of a small crater at the top of a low mound. (A binocular ophthalmoscope was not available.)

The macula of the left eye showed an identical process except that it was of extremely slight degree and would have been missed entirely in a routine fundus examination. There was an irregular and eccentric foveal reflex and very little pigment change, but the central crater, although small, was definite, and was easily seen by red-free light.

Examination of the peripheral vascular system resulted in the following observations, in a draft-free room, at a temperature of 70°F. Skin temperatures were taken with a flat-bulb skin thermometer protected by a cork near its tip: (1) mouth temperature, 98.4°F.; (2) temperature of big toe, 83.2°F.; (3) temperature of middle finger, 87.2°F.; (4) temperature of big toe, three minutes after smoking one cigarette, 75°F.; (5) temperature of big toe after diagnostic procaine block of posterior tibial nerve behind the internal malleolus, right foot, 94.3°F.; (6) capillary microscopy of the bed of the nail showed a high degree of capillary narrowing.

A number of practically identical cases have recently been carefully studied both ophthalmologically and psychiatrically by Zeligs,²² who approached the problem psychosomatically and pointed out the occurrence of anxiety (induced by combat) as a common-type factor in the production of central angiospastic retinopathy.

RETINAL CHANGES IN RAYNAUD'S DISEASE

The following definition of Raynaud's disease was formulated by the peripheral vascular clinic of the Massachusetts General Hospital:

"Raynaud's disease is a form of peripheral vascular disturbance caused by tonic contraction of the smaller arteries in the extremities. During the early, uncomplicated states of the disease, there are no obvious pathologic changes in the walls of the arteries. The disease commonly involves symmetrical areas in the hands and feet, causing circulatory stasis with periods of cyanosis or pallid asphyxia. The severe cases go on to dry gangrene of the phalanges. The spasm is intermittent and occurs on exposure to cold or emotional stimuli; it involves only the terminal arteries while the main vessels continue their normal pulsations. Frequently these patients complain of excessive perspiration which is also limited to the extremities. The disease most commonly occurs in young individuals with hyperirritable nervous constitutions" (White and Smithwick⁸).

While the occurrence of the clinical entity described by Maurice Raynaud²³ is relatively uncommon, every student of peripheral vascular disturbances has encountered instances of acrocyanosis and all varieties and degrees of peripheral vasospasm. For practical purposes these may be assumed to be identical except in the intensity and duration of the spasm. Frequently these cases of mild vasospasm have been precipitated into typical Raynaud's disease. In true Raynaud's disease as well as in the borderline cases, hyperhidrosis is a prominent feature. This has also been seen to be a characteristic of the vasoneurotic diatheses almost universally associated with central angiospastic retinopathy.

Raynaud and others^{24, 25, 26} have described attacks of intermittent constriction

of the retinal vessels with blurring and even permanent loss of vision and Bailliart²⁷ has described a complete choroidal anemia with destructive retinal lesions. While it is true that a vasomotor neurosis would be expected to affect primarily the hands and feet, it is also true that the smaller arterioles (the site of the vasospasm) might well be affected in other parts of the body.

There is still some difference of opinion concerning the etiology of Raynaud's disease, but the greatest weight of evidence upholds Raynaud's original idea; namely, that at the onset of the disease the recurrent attacks of symmetrical vasospasm are due to an abnormal activity of the vasoconstrictor nerves.

I have had an unusual opportunity to study two cases of well-advanced Raynaud's disease in young men both of whom showed ocular disturbances. The cases were practically identical both in peripheral vascular involvement and in the eye examination. Skin-temperature readings were obtained in only one case, the report of which follows.

CASE REPORT

C. D. D., a 19-year-old yeoman, second class, was admitted to the hospital on the Dermatologic Service because of small, painful, dry ulcerations at the tips of the fingers and of several toes. He had first noticed pain and numbness of the hands, associated with extreme pallor of the fingers, when exposed to cold weather aboard a small ship in northern latitudes. While on this ship, he frequently was exposed to severe cold and active exercise and excitement in spite of his yeoman's rating, as each member of the crew was required to stand watches regardless of rate. He complained as little as possible for fear of being considered a shirker, but there were times when, under the combined stimulus of cold, exercise, and

excitement, the pain and discomfort were so intense as to cause him to weep. He particularly noted the prolonged, almost dead-white pallor of his fingers after these episodes. Several months before admission, he was transferred ashore, where he was assigned to work involving considerable typing. He was much more comfortable, but soon noticed that, after a

points, with symmetrical areas of dry gangrene and loss of substance at the tips, especially just under the nail edge. After three minutes' elevation of the hands to the level of the ears, they became extremely pale and began to give pain. On dependence of the hands to his sides, they quickly became very cyanotic. The same was true of the feet. The radial

* Drop in temperature of big toe 3 minutes after finishing one cigarette.

† Spasm on basis of 1 to 4+.

Temperatures taken after 1 hour in a draft free room at 70°F.

few minutes of typing with his hands elevated to the typewriter keyboard at about the level of his nipples, the fingers became very pale and painful. He procured a high stool which lowered the level of his hands, and this helped for a while. During all this time, he had noticed that the small ulcerations on his finger tips failed to heal satisfactorily. His only ocular complaint was of periodic, somewhat disturbing blurring of his vision, especially in the right eye. These attacks would last for 5 to 15 minutes and were usually noticed when he was working under pressure to finish a piece of work in a specified time. He did not consider himself emotionally unstable nor nervous. He smoked 20 cigarettes a day.

Examination of his hands and feet showed typical symptoms of Raynaud's disease, including very wet, cold hands, and fingers that tapered almost to

and dorsalis pedis pulses were well palpated.

Ocular examination. Vision was: R.E., 20/30 blurred; L.E., 20/15. Refraction with cycloplegic showed a plus 0.75D. sphere for each eye, but without change in vision. Ophthalmoscopic examination was negative in the left eye, but the terminal branches of the superior temporal artery of the right eye showed definite and marked vasospasm and irregularity of caliber near the macula. The macula of the right eye showed a rather coarse granular pigmentation, with loss of foveal reflex and a generally "smeared" appearance. There was no loss of substance in the fovea. The appearance of the macula was identical with the late stages of a typical mild case of central angiospastic retinopathy.

Skin temperature readings on the right foot were as follows: (1) room tempera-

ture, 70°F.; (2) skin temperature, knee, 79°F.; (3) skin temperature, base of big toe, 70°F.; (4) skin temperature, base of big toe after one cigarette, 65°F.; (5) skin temperature, knee, after procaine nerve block, 82°F.

During the preparation of the patient for skin-temperature readings, there was noted marked increase in the sweating of the hands and feet and also such severe axillary sweating as to cause the patient embarrassment. After procaine nerve block, there was a prompt and spectacular decrease in the moistness of the treated foot.

AMAUROSIS FUGAX

Under this heading may be considered all those ocular disturbances that are transitory in nature, borderline in character, and that produce certain symptoms and signs due to autonomic instability, but leave no permanent, visible, organic change. These conditions may be listed as: (1) transitory visual loss under conditions of emotional stress; (2) visual disturbances under conditions of extreme fatigue, such as that seen in combat fatigue in the armed service.

Under the first of these headings may be placed the very numerous cases seen in young adolescents of somewhat unstable temperament, who manifest periodic "black out" under conditions of excitement, homesickness, worry, and the emotional shock of battle. Every medical officer in the Armed Forces has seen them in great numbers, and I have frequently seen them in civilian life in anxious medical students before or during an important examination. Within the past six months, I have so often encountered this symptom in patients with typical neuro-circulatory asthenia as to consider it of considerable importance as a diagnostic sign of that "disease." The patient is rarely sick enough to be hospitalized but

is seen in consultation in the out-patient clinic. His chief complaint is of frequent, periodic loss of vision in both eyes lasting upward of 30 seconds. The visual loss is described as a "fogging" of varying degree, sometimes culminating in complete "black out" as described by aviators at the termination of a dive, when the sudden change of direction of the plane forces the pilot downward so hard as to drain the blood from his cerebral vascular system (and possibly from the retina) into the extremities and splanchnic reservoirs. One outstanding case of this sort occurred in a fighter-plane pilot, who compared his periodic visual loss with that occurring in the "pull out" from a plane dive.

In all of these cases, there is definite, clinical evidence of hyperactivity of the sympathetic nervous system. Many of them show evidence of some degree of vasospasm, so that the tips of the fingers are cold and sometimes cyanotic. The most frequent and annoying associated symptom, however, is hyperhidrosis. These patients almost uniformly show a clammy wetness of the hands and feet which, under the mild psychic stress of questioning and examinations, becomes so marked that their hands drip beads of perspiration and everything they touch becomes wet. Also frequently noticed is a remarkable degree of axillary sweating, so that after a few minutes of questioning the patient is much embarrassed by large stains which appear on his shirt sleeves. There is no increase in generalized sweating, and comparisons of the patient's hands with those of medical corpsmen in the same room reveals a marked difference.

Careful ocular examination of these cases, including exhaustive muscle-balance tests, cycloplegic refraction, ophthalmoscopic examination, and visual-field tests revealed no objective findings of note.

Six men suffering from "combat fatigue" who complained of visual disturbance, have been seen in consultation with the neuropsychiatric departments. Of these, only one showed demonstrable organic change in the retina and some permanent visual disturbance. All six showed classical symptoms and history of

admitted that he frequently had been frightened and tense, and stated that this fear had increased in severity to such a degree that in the last few months of service every call to general quarters found him hyper-alert and trembling. Because of this nervousness, he had increased his cigarette consumption from

combat fatigue, with the additional rather unusual history of frequent, transitory, visual loss lasting from a few seconds to over a minute.

CASE REPORT

W. H., seaman first class, aged 25 years, was admitted to the hospital on the neuropsychiatric service with the diagnosis of combat fatigue. He had been stationed aboard a ship which had participated in four major sea battles and which had been twice struck by bombs and once by shell fire from an enemy cruiser. He had never been particularly nervous in temperament, had a very stable background, and a good family history. He

15 to 80 cigarettes a day. He first noted a blurring of vision following a night battle. After the action had broken off and the "secure" signal was given, he returned to his quarters to find that objects were blurred and "misty." In about a minute, vision cleared. He attributed this phenomenon to exposure to gun flashes near by and to his staring into the dark for so long. Shortly after this, he began to experience rather frequent attacks of blurred vision which seemed to occur when he was tired or excited. He states that these attacks were not associated with reading or other use of his eyes. Two weeks before entry to the hospital, his ship was struck by an enemy bomb.

The explosion was at some distance from him and although he was knocked up against the bulkhead, he was not dazed or otherwise hurt, except that he felt like he was "going all to pieces." He began to tremble violently and completely lost his vision. He was found by a medical corpsman groping about the deck on his hands and knees and crying, and was taken to the sick bay. His vision gradually returned, and he believes that the total elapsed time of the visual loss was not more than 15 minutes. Since that time, however, he felt that his vision was not so good as before.

On admission to the hospital, he was found to be very nervous and apprehensive, with definite tremor of the hands and marked sweating of the palms. He frequently experienced severe nightmares from which he awoke crying. The least noise elicited a severe "startle reaction."

Examination of the eyes showed vision to be: R.E., 20/40; L.E., 20/25. Refraction with cycloplegic showed, R.E., a + 0.50D. cyl. ax. 90°; L.E. +0.25D. sph. Vision was not improved by correction of this error. The macula of the right eye showed the typical granular pigmentation with loss of the foveal reflex seen in central-angiospasm retinopathy. The macula of the left eye was normal in appearance.

It was felt that this case might well be placed in the classification of angiospastic retinopathy, except that the organic findings were so minimal and the visual loss was of a transitory character until the final attack.

Under rest and sedation and a minimum of psychotherapy, the patient's general symptoms cleared rapidly.

Of retinal angiospasm in general, Duke-Elder²⁰ points out that its recognition as a cause of amaurosis fugax is of relatively recent date. It can be produced experimentally by injection of adrenalin or

of the serum of hypertensive individuals, or, in susceptible persons, by cold, or by the inhalation of tobacco smoke. The actual observation of spasmodic contractions of the retinal vessels, of fleeting duration, associated with similar vascular phenomena elsewhere and leaving no trace, has established the condition as a clinical entity.

Cases of retinal angiospasm occurring in young individuals who show no signs of organic retinal arterial diseases are frequently associated with evidence of vasomotor instability elsewhere.

MIGRAINE

Although typical ophthalmic migraine is a cerebral rather than an ocular disturbance, it can scarcely be doubted that it is of vasomotor origin. As its chief manifestations are ophthalmic, it is included here.

The incidence of typical ophthalmic migraine (with homonymous scintillating scotomas and transient homonymous hemianopia, followed by headache, nausea, vomiting, and prolonged lassitude) is extremely high in the armed services.

This may be because we are dealing almost exclusively with the age group commonly subject to the disorder. It has been my experience, however, that careful questioning of many individuals reveals a definite background of long-standing, mild vasomotor instability that has been markedly aggravated by psychic trauma incident to duties in the Service.

A typical case will frequently include a family history of migrainous attacks in the mother, or sibling, or both. The past history reveals infrequent, but typical, migrainous attacks beginning as early as 8 to 10 years of age. Cautious questions will elicit the information that these attacks were usually precipitated by an unpleasant experience or in anticipation of some disagreeable situation. On entering

the Service; the attacks usually increase in frequency and severity during early adjustment in boot camp and then subside somewhat, only to break out anew with a change of duty—particularly in anticipation of foreign duty. In at least two instances in officer personnel, a series of violent and completely disabling attacks were precipitated by assignments to new commands entailing greatly increased responsibility. In three cases, I have precipitated attacks, in which I was able to map out congruous homonymous hemianopias, by announcing to the patients that I was discharging them from the hospital back to full-duty status.

A large percentage of the cases of typical ophthalmic migraine which I have examined have shown clinical evidence of generalized vasomotor instability, as judged by the criteria set forth, especially hyperhidrosis.

In only one case was I able to demonstrate an actual spasm of a retinal vessel during the prodromal attack of scintillating scotoma, although this has been frequently described in the literature. In no case have any permanent organic ocular or cerebral changes been noted.

It is recognized that cognizance must be taken of the other theories of the etiology of migraine, such as precipitation of attacks by food allergy, but in the vast majority of the cases examined by me, the etiologic factor was almost undoubtedly vasomotor, and the usual precipitating factor was psychic trauma.

COMMOTIO RETINAE

Under this classification will be considered the retinal changes incident to localized vasospasm resulting from: (1) ocular contusion; (2) blast concussion; (3) solar burns.

In a recent letter to the Navy Department, Bureau of Medicine and Surgery

News Letter, Prof. Alton Ochsner²⁸ stated:

As a result of trauma, vasoconstriction of peripheral arteries invariably occurs. This is undoubtedly a protective mechanism and is life-saving at times. The trauma initiating the vasospasm can be of any type: mechanical, accidental, operative, thermal or actinic. The greatest degree of vasospasm is seen apparently in crushing injuries and in frost bite.

The degree of vasospasm varies considerably in different individuals. Under some conditions and in some individuals, the degree of vasospasm may be so slight as to produce few, if any, manifestations. On the other hand, it may be so severe as to produce such ischemia that gangrene may develop. This condition has been designated as "local shock."

In addition to the actual necrosis and interference with wound healing which may result from the vasospasm associated with trauma, there may occur interferences with sensations, particularly sympathalgia, the so-called causalgia which previously has been difficult to explain. Many individuals with this condition were considered as malingerers, since the location of their pain did not correspond to the distribution of the peripheral nerves.

With vasoconstriction due to mechanical, thermal, or actinic trauma, there is a secondary dilatation of the minute vessels in the area, as previously stated in the discussion of chemical control of the circulation.

As has been pointed out, substances of the nature of histamine are produced locally by the tissue cells as the direct result of any trauma sufficient to liberate histamine from the cells. The complete reaction produced by these histaminelike substances is a primary and local dilatation of the minute vessels, a local increase in the permeability of the capillary walls, and a widespread dilatation of neighboring arterioles.

The reactive hyperemia that occurs after obstruction of the circulation is an example of this dilatatory action of local-tissue metabolites. Heat, light, or ultraviolet radiation dilates the capillaries through the same mechanism of histamine liberation.

In considering commotio retinae, under which we have classified the retinal changes associated with ocular contusion, blast compression or concussion, and solar retinitis, we are dealing with morphologic changes in the macula which are practically identical in each case.

Duke-Elder²⁰ has pointed out that one of the sites of election for retinal edema is the macula. In states of circulatory edema, this is probably due largely to the structure of the thick fiber-layers of Henle, which absorb large quantities of fluid, and to the avascularity of the central area. Such edema follows contusions to the globe and probably depends, as in the brain, upon a sudden vasoconstriction followed by an extreme vasodilation.

In commotio retinae from whatever cause (contusion, concussion, or thermal), the ophthalmoscopic picture is practically identical, varying only in degree. It is so remarkably similar to the clinical picture seen in central angiospastic retinopathy and also in the two cases of Raynaud's disease previously described as to defy ophthalmoscopic differentiation.

In its milder aspects, the edema produced is sometimes difficult to see. The retina in the macular area looks thicker and somewhat translucent; with a finely granular appearance and a series of radiating, somewhat spokelike reflexes. Occasionally, the entire macula will be surrounded by a bright "halo reflex," such as has been described in connection with angiospastic retinopathy.

This edema may persist for days to weeks but gradually subsides, leaving in its wake a definite and sometimes marked redistribution of pigment. In many instances, this is imperceptibly followed by autolysis of the retina in the foveal area, with production of the typical "hole" in the macula.

The only difference between this picture and the classical Berlin's opacity,

with its milky clouding of the retina, is one of degree.

It was a striking clinical feature of all three types of commotio retinae that the majority of the patients complained rather bitterly of a nagging, boring type of orbital pain which was very persistent and similar in every respect to the pain noted so frequently in the angiospastic cases. It is thought that this is probably a form of causalgia or sympathalgia.

CONTUSION RETINOPATHY

Case 1. L. W., aged 22 years, was struck in the right eye by a hand ball. There was immediate and marked loss of vision and pain in the eye. Examination that same afternoon showed an injected eye with traumatic dilatation of the pupil, edema of the lid, free cells in the aqueous, but no hemorrhage. Vision was finger counting at two feet. The macula of the right eye showed the grayish, translucent appearance of a moderately severe Berlin's opacity, with elevation of the retina in the macular area. During the next few days, the vision improved rapidly and the retinal edema subsided. The patient complained of severe pain deep in the orbit "behind the eye." As vision improved, the tangent-screen field showed a small central scotoma for the 2/2,000 isopter.

At the end of a week, vision was 20/70 in the right eye, and the retina had regained its normal transparency, although it still showed some edema and a definite granular pigmentation of the macula. The foveal reflex was absent.

Two months later, reexamination showed a typical small "punched-out hole" in the macula, and vision was 20/30. The pain in the orbit was still present, although decreasing in severity. A minute central scotoma was still demonstrable, and there was definite metamorphopsia, as tested by the "music-staff" test at 14 inches.

Case 2. C. B. P., a 20-year-old corporal of Marines, was injured on Iwo Jima. A bullet went through the right maxilla from below the right ear and "exploded" in his mouth. A large hole was torn in the palate and into the right antrum. There was moderate exophthalmos of the right eye. On examination, 10 days after injury, vision of the right eye was 20/30. The macula showed definite and fairly marked edema with granular pigmentation around the fovea and striate folding of the retina around the fovea. Reexamination, three weeks later, showed subsidence of most of the retinal edema but with marked increase in foveal pigmentation and no improvement in corrected vision. No scotoma could be demonstrated, but metamorphopsia was fairly marked.

Case 3. H. E. E., a 21-year-old private of Marines, was pushing a 37 mm. gun over rough terrain on Iwo Jima when the gun ran over a land mine. The gun was blown to bits. The patient was behind the steel shield and sustained some shrapnel wounds in his legs and lower trunk, and a few in his arms and face. He was unconscious for two days. When he regained consciousness, he could not see from either eye for another two days. Then vision in the right eye gradually returned. He believes he was struck in the face by a piece of the gun as the lids of both eyes and his nose were severely swollen and bruised.

Examination, 16 days after the injury, showed vision to be R.E., 20/40; L.E., light perception. The left eye showed a dislocation of the lens medially through rupture of the lateral zonule. The macula of this eye showed a very marked gray edema, with a dark-red spot in the fovea. Next to the disc was a small streak of traumatic choroiditis, or rupture of the choroid.

The right eye showed a coarse, granular pigmentation with a faint halo around the macula, as seen in minor degrees of edema. There was a very small scotoma for a 1-mm. object at 1 M., just at the upper edge of fixation. The clinical picture was identical with that seen in a subsiding angiospastic retinopathy. The patient had many of the signs and symptoms of combat fatigue, such as, startle reaction, tremor, nightmares, and anxiety. He also showed marked sweating of the hands and some coolness of the fingers. It was considered that the left eye showed definite evidence of contusion, with secondary angiospastic retinopathy. The findings in the right eye could be due to minor contusion, blast compression, or even severe psychic trauma. They serve to demonstrate the similarity in all three forms regardless of the etiology.

BLAST CONCUSSION

Case 1. H. L. M., a Marine Corps second lieutenant, aged 26 years, was injured by the blast from an exploding ammunition dump which went off about 100 yds. from him. He thought that seven or eight men near him were immediately killed by the blast. At the moment of the explosion, he was in a foxhole leaning down in an attempt to help his commanding officer, who had been injured by shell fire. Although he was blown from the hole, he was not struck by shell fragments and felt that the force of the blast was broken, thus saving his life. He was unconscious for six days and suffered some bleeding from ears and nose. Both ear drums were ruptured, but quickly healed. When he regained consciousness, he was almost completely deaf, and vision was little more than good light perception. Both hearing and vision rapidly improved, and in five days, vision was recorded as: R.E., 20/30; L.E., 20/40. On examination, three weeks after injury,

vision was: R.E., 20/25; L.E., 20/30; corrected to 20/25 (blurred) in each eye with a $-0.50D.$ cyl. ax. 90° . He had previously always had 20/20 vision, uncorrected, in each eye. Hearing was decreased in the right ear, 20 percent; in the left ear, 50 percent.

Both maculas showed granular pigmentation with some residual edema. The fovea of the left eye showed a minute, sharply outlined, red spot which looked like a small crater. No scotoma was demonstrated but metamorphopsia could easily be elicited in the left eye. The patient had shown some signs of combat fatigue including a severe tremor and very marked hyperhidrosis, but these had practically disappeared after three weeks, and he was anxious to return to duty.

Case 2. V. J. P., a 22-year-old seaman, first class, was blown 10 ft. or more across the deck of his ship by the explosion of a Japanese suicide dive bomber, containing a warhead which struck the ship. He thinks he was about 30 ft. from the plane when it struck. He was unconscious for several minutes, and there were several casualties near him. When he regained consciousness, he was blind but otherwise unhurt, except for some minor lacerations about the face and chest. He was disoriented, dazed, and almost completely blind for two days. Vision gradually improved in both eyes but remained blurred in the right eye. Examination, two weeks after the injury, showed vision to be: R.E., 20/40; L.E., 20/20. External examination of both eyes and X-ray pictures of both orbits were negative. Pupils were normal and media clear. The fundus of the left eye was normal; that of the right eye showed a grayish, translucent edema of the entire macula, with a small reddish spot in the center. Tangent-screen field showed a 2° central scotoma for the $1/2,000$ isopter.

Reexamination in two weeks showed the retinal edema to have partially subsided but to be still easily visible, with considerable increase in foveal pigmentation and the appearance of an early hole in the macula. There was no evidence or history of contusion of the eye by a solid object.

SOLAR RETINITIS

Only two cases have been seen which I felt could be unquestionably called solar retinitis. Many cases of macular pigmentation, macular edema, and hole in the macula have been reported from the Pacific area of war and have been attributed to damage by actinic rays because of their history of exposure to glare from coral sand and water. Thygeson²⁹ reports seeing many such cases in aviators after repeated high-altitude flights. It is possible that some of these cases were actually due to the action of infrared or ultraviolet rays on a sensitive retina. Their description, however, tallies much more nearly, both as to subjective symptoms and objective signs, with angiospastic retinopathy produced by vasomotor disturbances initiated by psychic trauma, fatigue, or increased use of tobacco in an autonomically unstable individual.

I have seen some of these cases returned to the United States from the Southwest Pacific with the diagnosis of actinic-ray ophthalmia and have compared them with severe cases of central angiospastic retinopathy from the Aleutian Islands area where exposure to the sun was not an etiologic factor. In their end stages, they are clinically identical.

Some years ago Verhoeff and Bell³⁰ exposed an eye that was to be enucleated to prolonged ultraviolet irradiation with resulting loss of vision but with very rapid recovery. They were unable to demonstrate any retinal lesions due to ultraviolet rays.

The same authors showed that the

effects known as "eclipse burn of the retina" were wholly thermic and due to concentration of solar energy upon the retina by the refractive system of the eye itself. Although there have been undoubted examples of eclipse blindness, the majority of such cases give but a vague and indefinite history of exposure and visual loss.

In the two cases of solar retinitis to be reported, there was unquestioned exposure to direct sun rays, augmented by concentration of the rays by optical instruments.

Cordes,¹⁹ in his report for the National Research Council, cites several practically identical cases described to him by various Naval medical officers.

Case 1. W. H., a 26-year-old seaman, first class, was stationed as lookout on a small aircraft carrier. He was using a monocular telescope and searching for enemy planes. Since, in attacking, the planes usually "come in from the sun," he had kept his glass focused in that general direction and had noticed several transient blurrings of vision which, however, rapidly cleared. Upon receiving a report that planes were approaching, he had looked directly into the sun and immediately noticed a very sharp and severe pain in the eye and a complete obscuration of vision. The pain continued to be very intense and seemed to be located deep in the eye or orbit. Vision was limited to light perception. Upon examination in the sick bay, a note of "a marked haziness of all the retina temporal to the disc" was made in his health record. When hospitalized one month later, vision in the right eye was reduced to 20/200. There was still some edema of the macula of the right eye and considerable pigment disturbance; the fovea was replaced by a deep-red, "punched-out" hole. The pain in the eye was still severe.

Case 2. P. J. T., a boatswain's mate, second class, aged 29 years, was acting as lookout aboard his ship and inadvertently followed a plane directly "into the sun" with a pair of binoculars. There was immediate severe pain in both eyes and marked loss of vision so that he had to be led into sick bay, where examination showed a "grayness of both retinas temporal to the disc, with a small hemorrhage in its center." It is thought that this "hemorrhage" was the red spot in the fovea which, when seen three days later, showed the typical picture of bilateral Berlin's opacity of the macula.

Vision was reduced to 4/200 in each eye, upon examination in the hospital. There was gradual improvement in vision during the next month and when last seen, vision was: R.E., 20/70; L.E., 20/100. There was a heavy granular pigmentation of both maculas, with sharply outlined holes developing in both foveae.

These lesions are thought to be the result of localized vasospasm of the retinal arterioles and capillaries in the macula initiated by thermal or infrared rays and followed by compensatory vasodilation, increased capillary permeability, severe edema, autolysis of the retina, and, finally, hole in the macula.

SUMMARY AND CONCLUSIONS

1. The relationships between the eye and the autonomic nervous system are reviewed with special reference to possible effects on ocular physiology.

2. The autonomic stimuli are enumerated and found to be intensely active under wartime conditions of living. Special emphasis is placed on the importance and frequency of psychic trauma as a cause of autonomic instability and of the production of both physiologic or functional and pathologic or organic ocular changes.

3. Clinical studies have been made on autonomically unstable individuals, including certain studies on the peripheral vascular system. These have been correlated with certain physiologic dysfunctions and pathologic changes in the retina.

4. The clinical picture of vasoneurotic diathesis of the autonomically unstable person is described, and it is noted that the only constant factor in all cases of central angiospastic retinopathy is this autonomic instability.

5. The ocular manifestations of autonomic-nervous-system dysfunction reported were as follows: (a) central angiospastic retinopathy; (b) ocular changes in Raynaud's disease; (c) amaurosis fugax; (d) migraine; (e) commotio retinae. Typical case reports of each condition are presented.

6. It is emphasized that the differences between amaurosis fugax, central angio-

spastic retinopathy, and Raynaud's disease are those of degree only.

7. The condition known as Migraine is a cerebral vasospastic disturbance with predominant ocular symptoms.

8. Commotio retinae, which embraces all conditions producing retinal edema from chemical vasomotor disturbances, is a local rather than a general autonomic response.

9. Psychic trauma in a susceptible individual can produce as profound organic changes in connection with the autonomic nervous system as extremes of temperature, anoxemia, or direct physical trauma. The greatly increased wartime incidence of certain disturbances of autonomic origin can be explained in no other way.

10. The almost constant association of pain with these ocular lesions can best be explained as causalgia or sympathalgia.

PEMPHIGUS CONJUNCTIVAE*

REPORT OF THREE CASES

FRANK W. NEWELL, MAJOR (MC), A.U.S., AND
JAMES S. GREETHAM, MAJOR (MC), A.U.S.

Pemphigus conjunctivae is a slowly progressive, chronic, cicatrizing, keratoconjunctivitis of unknown etiology, frequently associated with vesicular lesions of the mucous membranes and occasionally with cutaneous involvement. It is characterized by an absence of constitutional symptoms and a benign course as concerns life.

Pemphigus is usually classified as acute and chronic pemphigus vulgaris, pemphigus vegetans, pemphigus foliaceus, pemphigus erythematosus (Seneear-Usher), and pemphigus conjunctivae or benign mucous-membrane pemphigus. The latter type has been described as a distinct entity by Klauder and Cowan,¹ who distinguish it from chronic conjunctival shrinkage and scarring accompanying a number of skin diseases, most of which exhibit blebs (bullous eruption following vaccination, dermatitis herpetiformis, erythrodermia ichthyosiformis, and epidermolysis bullosa dystrophica). The condition known as acute ocular pemphigus and characterized by a pseudomembranous conjunctivitis, stomatitis, severe prostration, and a cutaneous eruption is classified by them as a severe atypical form of erythema exudativum multiforme (Hebra).

The incidence of pemphigus conjunctivae is probably greater than previously believed. Lever and Talbott² saw 62 cases of pemphigus at Massachusetts General Hospital between 1921 and 1936, 10 of which (16 percent) were of the conjunctival type. Rycroft³ saw four cases at

Moorfield's in five years and believed the disease was not uncommon. Cutaneous pemphigus, particularly pemphigus vulgaris, is more common and is associated with a higher mortality in Jews, but no racial difference has been noted in the conjunctival type. There is a relatively even distribution between sexes in the cutaneous types, but the conjunctival form occurs more commonly in the female. The disease is usually one of later life, the average age in Lever and Talbott's² series of 10 cases being 61.6 years.

Parsons⁴ states that early in the disease the conjunctiva shows considerable swelling due to edema and lymphoid infiltration. Later, the conjunctival epithelium is much thickened and sends coarse plugs into the subconjunctival tissue. There is marked infiltration of the submucosa with round and spindle cells and enormous hypertrophy of fibrous tissue.

Lever and Talbott⁵ found a reduction in blood-serum protein, sodium, calcium, and chlorides in acute and chronic pemphigus vulgaris and pemphigus vegetans but no serum abnormalities in the conjunctival type. Mulvehill⁶ found consistently low serum albumin fractions in 10 cases of pemphigus but in no case was there ocular involvement. Pels and Macht⁷ have devised a test which depends upon marked inhibition of growth of *Lupinus albus* seedlings when immersed in a nutrient solution containing pemphigus blood serum. It has been positive in all types of pemphigus including pemphigus conjunctivae.

There are no symptoms characteristic of the ocular phase of the disease. Ini-

*From the Surgical Eye Center, Wakeman General Hospital, Camp Atterbury, Indiana.

tially, patients complain of a moderate photophobia, burning, itching, and similar complaints associated with a mild, chronic conjunctivitis. In the later stages, intermittent conjunctival injection, dryness, and persistent foamy, ropy secretion are most prominent. Formation of symblepharon and conjunctival scarring develops insidiously and without a readily apparent ocular inflammation. Cicatricial contracture may cause trichiasis, and the symblepharon may become so extensive as to cause complete ankyloblepharon with ultimate loss of the globe. The cornea may be covered with a cuticularlike membrane with serious diminution of vision long before involvement secondary to complete ankyloblepharon.

The mucous membranes of the nasal pharynx, mouth, esophagus, rectum, and vagina are frequently involved. Early, there are vesicles of varying size which eventually rupture, leaving macerated areas. These areas heal slowly and result in atrophic scarring and contracture with deformity in the part involved.

The skin is infrequently involved according to most writers. However, Urbach⁸ states that pemphigus of mucous membranes may exist for one, two, or three years, and then suddenly break out over the entire body. The skin eruption is usually localized particularly on the face and initially presents blebs which rupture and then crust. The lesions heal slowly without scarring. The presence of cicatricial changes in the skin has been described rarely, Lever⁹ finding but five cases previously reported to which he added six of his own.

Numerous theories as to the cause of pemphigus have been proposed but none confirmed. Among these theories are the toxic, neurotropic, infectious (*B. pyocyaneus*, *B. pemphigus*, *B. streptococcus*), vitamin deficiency, virus (Urbach), and suprarenal insufficiency. Recently Gal-

lardo and Hardy¹⁰ isolated a virus closely related to the vaccinia virus in a case of pemphiguslike keratoconjunctivitis.

The status of treatment of pemphigus has not changed since 1930, when Riecke¹¹ wrote: "Pemphigus shows such a fitful and paradoxical spontaneous course that only too easily can erroneous conclusions on the value or lack of value of any line of treatment be drawn." This statement is emphasized by the number of drugs which have been recommended and condemned. In the text by Ormsby and Montgomery,¹² the following treatments are mentioned: quinine, arsenic as sodium arsenate, acetarsone (stovarsol), salver-san, cacodylate of iron, tryparsamide, soluble mercurochrome, moccasin venom, germanin, exclusion of salt from diet, colonic irrigations, strychnine, autogenous vaccine, cod-liver-oil and malt preparations, viosterol, and sulfanilamide. Recently, in a careful study, Lever and Talbott⁵ have used adrenal-cortical extract and dyhydrotachysterol with encouraging results in all except pemphigus conjunctivae, in which the course of the disease in two patients was not affected.

Trichiasis and xerosis are frequent ocular complications. Dimitry¹³ recently recommended the use of choline as a wetting agent in ocular pemphigus and stated that the local use of the drug has made epilation unnecessary. The Van Milligan operation is of transient value only, as the transplanted mucous membrane is eventually converted to scar tissue together with the adjacent conjunctiva. Surgical separation of the symblepharon is of no value, for the adhesions re-form, in spite of any agent placed between the epithelial surfaces.

CASE REPORTS

Case 1. A 26-year-old, white soldier, was admitted to Wakeman General Hospital, November 19, 1945, complaining of

recurrent redness of the eyes. He stated that, while hospitalized for pneumonia in November, 1944, he had developed a mucopurulent conjunctivitis which had recurred intermittently ever since. In July, 1945, a severe skin inflammation, diagnosed as impetiginous dermatitis, cleared with penicillin systemically, but since then had recurred about the face every few weeks. When 4 years old, he had a severe dermatitis with sores over the body and, when aged 9 years, had an empyema which necessitated a rib resection. He gave a history of high fever and general prostration whenever he received sulfonamide drugs.

Uncorrected vision in each eye was 20/20. The conjunctiva was atrophic and deeply scarred, particularly over the tarsi. A ropy, white secretion was present in the inferior fornices. The cul-de-sacs were markedly shortened and contained linear, horizontal, white scars which were elevated above the adjacent conjunctiva. Symblepharon bound the atrophic caruncles to the lower lids, and the semilunar folds were obliterated by adhesions between their free edges and the globe. A symblepharon extended from the inner margin of the upper lid to the globe, and traction of the lid resulted in an ischemic linear area extending from the point of adhesion to the corneal limbus.

Physical examination showed bilateral, chronic, maxillary sinusitis and right basilar bronchiectasis, which were asymptomatic.

Blood-serum protein, chlorides, calcium, cholesterol, nonprotein nitrogen, sugar, and sedimentation rate were normal. Agglutination for brucella and tularemia were negative as were the Kahn, Frei, and Mantoux tests. The white blood count was within normal limits, and the differential showed no abnormality other than an eosinophile count of 4 to 6 percent.

A small section of the right, lower lid was normal except for moderate round-cell infiltration of the subepithelial tissue.

At no time were vesicles of the conjunctiva, mouth, or pharynx noted and, other than the conjunctiva, there was no mucous-membrane involvement. Crusting lesions of the face were present intermittently and responded quickly to penicillin intramuscularly. Penicillin (1,000 units to 1 c.c. in solution) used locally in the eyes caused much of the secretion to disappear and seemed to limit the number of attacks of the conjunctival inflammation, but the condition remained essentially unchanged during four months of hospitalization.

Case 2. A 28-year-old, white soldier was admitted to Wakeman General Hospital, January 15, 1946, complaining of dryness and recurrent inflammation of the eyes present since March, 1942. He had been hospitalized at that time for pneumonia and treated with a sulfonamide drug to which he was sensitive. A concomitant conjunctival infection was treated with sulfathiazole ointment and caused a severe local reaction. Since then, the ocular inflammation had recurred periodically but was not incapacitating.

Vision was 20/70 in each eye corrected to 20/30 with a $-1.25D.$ sph. $\odot +3.50D.$ cyl. ax. 90° in the right eye; and a $-1.00D.$ sph. $\odot +3.00D.$ cyl. ax. 95° in the left. The palpebral conjunctiva showed diffuse atrophic scarring and several symblepharon extended from the inner margin of the upper lid to the globe. The semilunar folds were obliterated by adhesions, but the caruncles showed no scarring. In the outer portion of each inferior cul-de-sac, the conjunctiva was thrown into folds and appeared redundant but was firmly adherent to the underlying tissue. The remainder of the ocular examination was negative.

The hard palate showed white scars extending from the teeth to the median raphe, and, on one occasion, a macerated, red area was present on the buccal mucosa of the cheek. Vesicles formed occasionally on the gums and ruptured but did not appear to cause scarring. A vertical, linear scar was present on the left inferior turbinate. The remainder of the physical examination was negative.

Blood-serum protein, chlorides, calcium, cholesterol, sugar, and sedimentation rate were within normal limits. The Kahn, Frei, and Mantoux tests were negative, as were agglutination for brucella and tularemia. The white blood count was normal and showed 2-percent eosinophiles. A small section of tissue removed from the left, lower eyelid revealed no pathologic changes.

The patient's condition remained unchanged during hospitalization. Vesicles of the gum and mild, recurrent conjunctival injection were the only evidence of activity. The skin was not involved at any time.

Case 3. A 23-year-old, white soldier was admitted to Wakeman General Hospital, from overseas, May 30, 1945, complaining of diminution of vision and marked weakness. He had been wounded in the right foot and taken prisoner in Germany, November 15, 1944. While hospitalized for the foot wound, he developed a severe dermatitis of the head and neck which caused his eyelids to swell to complete closure. He was treated at an eye clinic, and the inflammation subsided, but vision was severely impaired. After recapture in April, 1945, the diagnosis of pemphigus conjunctivae was suggested by H. A. Mosher, Capt. (MC), at an Army General Hospital in Europe. In the course of evacuation to the United States, the patient developed a weakness of the lower extremities and was unable to walk.

He stated that impetigo had covered his body in 1943 and had disappeared without residue. Other than this, his medical history prior to capture was essentially negative.

Vision was: R.E. 20/300, corrected to 20/40 with a +3.75D. sph. \ominus -7.00D. cyl. ax. 40°; L.E., 20/400, corrected to

Fig. 1 (Newell and Greetham). Case 3. Symblepharon involving cornea.

20/50 with a -1.25D. sph. \ominus -1.75D. cyl. ax. 45°. The conjunctiva was shrunken, diffusely cicatrized, and pale in appearance, with many blood vessels obliterated by scar tissue. The cul-de-sacs were shallow, the caruncles scarred with numerous discrete linear areas, and the semilunar folds obliterated. A large number of symblepharon were present in the superior fornices, which were adherent to the globe. The left eye showed a heavy symblepharon which swept down from the superior lid margin to the inner one half of the cornea. A diffuse opacity, deep in the substantia propria, was present immediately temporal to the attachment of the symblepharon to the cornea. A large number of superficial epithelial opacities were present bilaterally. The circumference of the limbus showed diffuse clouding of the substantia propria extending inward 2 to 4 mm. and covered

with superficial, new blood vessels which, in some areas, extended beyond the opacity. The irides were slightly atrophic and bound to the anterior lens capsule by numerous darkly pigmented synechiae. The anterior capsule of each lens was diffusely opaque, particularly the left. There was no aqueous flare, and the remainder of the ocular examination was negative.

Physical examination revealed a healed bullet wound of the right foot, generalized muscle tenderness, absence of the cremasteric and patellar reflexes, and a hypoaesthesia to the level of the second lumbar segment. The skin of the posterior surface of the right calf and anterior surface of the left wrist showed circular, atrophic scars, measuring 2 cm. in diameter, depigmented centrally, with a ring of pigment at the periphery.

Blood-serum protein, chlorides, calcium, cholesterol, nonprotein nitrogen, and sedimentation rate were normal. The albumin-globulin ratio was reversed on several occasions. Agglutination for brucella and tularemia were negative as were the Frei, Kahn, and Mantoux tests. White blood count was normal, but the differential showed 5-percent eosinophiles.

The patient was placed on a high caloric, high nitrogen, and high fat diet, supplemented by vitamins orally and parenterally, and given 300,000 units of penicillin intramuscularly in divided doses. In several weeks, the muscle tenderness and hypoaesthesia disappeared, and the deep-tendon reflexes returned. Locally, atropine, adrenalin, cocaine, and neosynephrine were used in an attempt to break the posterior synechiae, and penicillin was used as an antiseptic. The cataract in the left eye progressed to maturity and vision diminished to light perception. On several occasions, multiloculated vesicles were noted at the corneal limbus of the right eye and on the conjunctival surface

of the lower lids. They did not rupture on repeated examination and disappeared spontaneously after four or five days. They were not associated with gross inflammation of the eye and did not give rise to symptoms. There has been no increase in the number of symblepharon since admission to this Hospital, and the lens opacity in the right eye has remained stationary.

COMMENT

A number of eye and skin diseases associated with conjunctival scarring and shrinkage were considered in making the diagnosis of pemphigus conjunctivae in these patients. There was no history of ocular injury with chemical agents, and the onset of the disease was not associated with vaccination. Trachoma was excluded in the absence of corneal involvement with typical pannus formation, lack of papillary hyperplasia, and the large amount of symblepharon formation. Erythrodermia ichthyosiformis and epidermolysis bullosa dystrophica are largely congenital conditions and have their onset in infancy. The absence of pruritic skin lesions, lack of involvement of the skin of the sacral triangle and scapular area ruled out dermatitis herpetiformis. The iodine-patch test was also negative in each of these patients and, while not absolutely diagnostic, indicated the disease was not dermatitis herpetiformis.

Grönblad¹⁴ has described conjunctival shrinkage following sensitivity to luminal, and Kasselberg¹⁵ has described a pemphiguslike skin eruption with symblepharon formation occurring in a patient sensitive to sulfamerazine. In that both Cases 1 and 2 gave a history of sensitivity to sulfonamides, it is possible that the ocular condition represented a drug sensitivity rather than pemphigus conjunctivae. The occurrence of vesicles in the mouth in Case 2 long after the drug was used led us to believe, however, that

the condition was not one of drug sensitivity. The large number of adhesions and the intermittent conjunctival injection continuing after the drug was discontinued indicated that the condition was most likely pemphigus conjunctivae in both cases.

The reversal of the blood-serum, albumin-globulin ratio observed in Case 3 was probably caused by nutritional deficiency rather than by pemphigus conjunctivae. The low degree of eosinophilia in each case is consistent with previous reports and is in contrast to the large in-

crease in eosinophiles commonly seen in cutaneous pemphigus.

Bilateral uveitis with complicated cataract formation, as was present in Case 3, has not, to our knowledge, been reported previously as occurring in pemphigus. Although no etiologic factor was found, we believe that it occurred coincidentally rather than secondary to the pemphigus conjunctivae.

Penicillin was of no value in the treatment of the disease except that it appeared to lessen the amount of ocular secretion when used locally.

THE EFFECTS OF ATABRINE ON THE HUMAN VISUAL SYSTEM*

LAWRENCE R. DAME, LT. COL. (MC), A.U.S.

Atabrine (Quinacrine hydrochloride) is widely used today in the treatment of malaria. A review of the available literature fails to reveal reference to any temporary or permanent effects of this drug upon the human visual system. To this end, a study was undertaken to investigate (a) visual changes with increasing blood-atabrine levels, (b) any alteration with decreasing atabrine levels, and (c) the effects on vision of long-continued atabrine administration.

HISTORY

In the early campaigns in the Southwest Pacific area, malaria inflicted the greatest number of casualties, with a resultant serious impairment of the military effort. Quinine was limited and ineffectual. Atabrine was first used in widely varying dosages, and many side effects and clinical observations have already been recorded in the literature.

Most malaria was of the tertian form. There were many somatic complaints, including retrobulbar pains which were often aggravated by ocular effort. In many instances, these were definitely connected by the patient with a specific malarial recurrence. Refractive errors varied widely, and neuromuscular abnormalities were rarely seen. While perimetric examinations were invariably normal, a high rate of various-sized scotomas were found, seemingly proportional to the number of malarial recurrences. Finally, a group of our own medical officers returned from tropical service with some of the previously noted symptoms and changes.

Many other factors of possible etiology with unknown influence had to be considered: Retinal fatigue due to the tropical sunlight; cerebral fatigue and mental disturbances after combat; constitutional exhaustion following marked loss of weight common to combat; febrile tropical disease such as dysentery and dengue; and, lastly, the unknown toxic action of atabrine.

Solution of this problem was indicated, but the individual normal for each patient's system could not be determined in retrospect. Fortuitous circumstances permitted a scientific approach to the problem in that our organization, an affiliated general hospital, had been established for two years in an isolated subtropical section of Australia where the combat factors were absent and the use of any anti-malarial drug had not been necessary. Furthermore, a change to tropical service was imminent. All of the illnesses and temperaments of the coöperating 39 officers with the requisite normal ocular systems and 6 others with minor small scotomas were well known. Because of these circumstances it was hoped to exclude all factors except those possibly connected with atabrine administration.

PART I: PROCEDURE

The basic preliminary examination of the visual tracts included the external inspection, the determination of visual acuities, neutralization of refractive errors with the aid of full homatropine cycloplegia, the detection of neuromuscular abnormalities, perimetric (1/2000/white and 3/330/white, blue and red/9 candlepower) and tangent screen (1/ and 6/2,000/white) investigations, and the actual sketching of the disc portion

* From the Eye, Ear, Nose, and Throat Section, Surgical Service, 105th General Hospital.

of the fundus. For the purposes of this investigation atabrine was issued in an experimental combination of dosages which individually were then officially recommended² in the Southwest Pacific area: 0.1 gm. daily, as in the suppression of clinical malaria (two weeks); 0.2 gms. daily, as in the rapid atabrinization obtained when approaching a hyperendemic area (one week); and in successive daily dosages of 1.2, 0.9, 0.3, 0.3, and 0.3 gm., as in full antimalarial atabrinization. Observations could thus be made at the different blood-atabrine levels. In actual clinical practice, a full course of atabrine for treatment would never be required immediately following 0.2 gm. per day for one week. The Chiefs of the Medical and Surgical Services selected eight of the volunteers to act as controls.

On the 7th, 14th, 21st, and 28th days, the basic examination was repeated except for the checking of the refractive errors. The laboratory determination of the blood-atabrine levels for the individual officers had to be discontinued because

FINDINGS

Of the 45 officers who entered upon this part of the investigation, 6 controls and 32 taking atabrine completed it. The following data were recorded concerning of the 32 taking atabrine:

1. There were no changes in external appearance, in central visual acuity, in extent of fields with white or colored targets, or in neuromuscular action.

2. Tangent-screen examinations revealed that field changes appeared: (a) 17 officers developed 41 scotomas averaging 12.9 by 15.7 cm. in size. Twenty-four of these were within 20 degrees of the fixation point and varied in period of onset and in duration. (b) There was a gradual minor increase (to a total of 1 cm.) in the size of the blind spots, with increasing blood-atabrine levels. (c) The five initial scotomas showed decreased size in two cases, no change in one case, and increase with development of a second scotoma in two cases. (d) Ten officers had no demonstrable changes. (e) The changes may be tabulated as follows:

Start	16 gamma per liter calculated		30 gamma per liter calculated		79 gamma per liter calculated	
	1st week	2d week	3d week	4th week	5th week	
Subjects	5	6	8	13	12	8
Scotomasa	7	9	15	19	26	11

of technical difficulties. The theoretical group levels (based on the extensive studies at the Fort Knox Armored Research Laboratory, as reported in December, 1943)¹ were:

	Gamma per Liter
14 days at 0.1 gm.	16
additional	
7 days at 0.2 gm.	30
1 day at 1.2 gm.	67
1 day at 0.9 gm.	79
4 days at 0.3 gm.	73

3. Retinal changes found on ophthalmoscopic examination were limited to a slight increase in the pinkness of the discs. No capillary measurements were made.

4. Complications. Some of the clinical observations previously recorded by other authors³ appeared in this study and are sufficiently pertinent to mention briefly: (a) Four officers had serious mental changes during atabrine levels of the fourth week. One required confinement in the closed psychotic ward; a second was considered for similar treatment;

and two others were sufficiently confused to require temporary relief from duty. All returned to normal with the cessation of medication. (b) Nineteen of the other officers exhibited the minor cerebral and gastro-intestinal stimulations reported by other authors.

Of the six controls, three developed six temporary scotomas (3 each with 1/ and 6/2,000/white) during the 2nd and 3rd weeks after a positive blood-alcohol level.

PART II: PROCEDURE

Atabrine was discontinued on the 29th day. In the period from the 60th to the 74th days, the examinations were repeated except for the 3/330 perimetries (equipment crated) and the check of refractive errors.

FINDINGS

All but five of the scotomas developed during Part I disappeared. The remaining scotomas were unchanged and were found in three individuals.

PART III: PROCEDURE

Atabrine was recommenced on the 125th day, when approaching the tropics: 0.2 gm. daily for seven days was administered, followed by 0.1 gm. daily throughout the stay in the tropics. The same expert technicians and equipment were used, and the illumination was carefully reduplicated and checked with a light meter.

The basic examination, except for the refraction portion, was repeated in the period from 243rd to the 317th days, when it was considered that the investigation

was of sufficient duration for definitive impressions to have been established. The earlier final determinations were necessitated by the impending separation of the individual from the organization for duty elsewhere.

FINDINGS

Of 36 officers completing this section, 6 new scotomas of the previously found average size were present in three subjects. There were no other changes from the normal.

SUMMARY AND CONCLUSIONS

An investigation of the effects of atabrine upon the human visual system was completed under advantageous circumstances. The blood-atabrine group levels rose to a calculated 79 gamma per liter under circumstances not to be expected in clinical practice.

Scotomas and blind-spot enlargement of minor importance accompanied the suddenly attained high blood-atabrine levels and disappeared with the lowering of the levels.

No other changes occurred in the human visual system during brief or prolonged atabrine administration.

There were no visual-system contraindications to the use of atabrine.

DUST-BORNE INFECTION IN OPHTHALMIC SURGERY*

M. HAYWARD POST, M.D.

Saint Louis

Asepsis in ophthalmic surgery has long been a problem peculiar unto itself. Of late years, there has been a tendency to conform more closely to the ideas of general surgery—such as the wearing of rubber gloves. But the incidence of infection still remains only slightly altered.

It is well known that by no possible method can the conjunctiva be rendered completely sterile. The discussion concerning the value of cultures taken before operation still finds proponents on both sides of the question. Fortunately for surgery upon the eye, the lysozyme of the tears shows a high bactericidal potency, and the lacrimal apparatus is so constructed that the wounds made at operation are constantly bathed in tears following these operations.

The wonder is not that there is still a certain percentage of infection, but rather that the incidence is so small. This fact, however, should give no grounds for complacency. There is nothing more harrowing in the experience of the ophthalmic surgeon than the discovery of an eye bathed in pus at the first postoperative dressing. Even with all our recent advances in bactericidal drugs and therapy, seldom, indeed, can such a situation be saved. It, therefore, behooves us to search in every direction for any additional precautions that may prevent such tragedies.

During the years of 1926 and 1927, the late Dr. A. E. Ewing was experimenting with various solutions that might sterilize the sharp instruments used in ophthalmic operations without injury to them. By his

work, I was stimulated to investigate this problem. My first paper on the subject appeared in the *American Journal of Ophthalmology*, in 1928.¹ The second was presented before this society in 1940,² and the third, written in conjunction with Mr. William Moor, was published in the *American Journal of Ophthalmology* in 1942.³ For reasons elaborated in the second paper, the most practical, all-around satisfactory method of accomplishing the desired results appeared to be by means of chemical solutions. That recommended in the last of these three papers, known as No. 4, has been in use by the Department of Ophthalmology of Washington University in all eye surgery since about February 1, 1941. The formula may be written:

Liquor cresolis compound	8.0 c.c.
Oil of lavender	2.0 c.c.
Thymol crystals	2.0 gm.
Ethyl alcohol 95%	88.0 c.c.

Mr. Moor and I were able to demonstrate by experiments recorded in that paper that clean instruments contaminated by cultures made up of various types of virulent organisms could be sterilized by immersion in that solution for a period of one-half minute. Four and one-half minutes, however, were required to sterilize similar instruments, previously soiled by blood and serum, when subjected to the same cultures, plus a heavy concentration of spore-bearing hay bacilli.

It was demonstrated that knives, dropper bulbs, and the like, immersed in this solution for very long periods of time, suffered no deterioration. Three knives, referred to in the third paper, have remained in it since November 14, 1940. They show no dulling of the edges, nor

*From the Department of Ophthalmology, Washington University School of Medicine. Read at the eighty-first annual meeting of the American Ophthalmological Society at Hot Springs, Virginia, November, 1945.

injury to the handles other than an increased translucency of the ivory of one of them. The aluminum and the nickel-plated brass handles of the other two show no change whatsoever. Nor has there been any electrolytic action among the three, despite close contact throughout this long period of immersion. Two rubber bulbs were likewise unaffected in any way after $2\frac{1}{2}$ years. Nor have any of the undesirable effects upon aluminum, encountered in the use of the germicide recommended in the second paper, in which formaldehyde was one of the constituents, been encountered with this solution.

During the past summer, and especially during the month of September, several infections having occurred in the eyes of patients operated upon for cataract in McMillan Hospital, of the Washington University School of Medicine, it seemed desirable to recheck the tests previously made, this time under operating-room conditions, and, also, while studying the action of the germicide, to conduct other experiments with a view to a determination of where contamination might be taking place, should it prove that the sterilizing solution was acting in a satisfactory manner.

Consideration of all the possibilities shows that such infections take place through: (1) contamination residual in the conjunctiva, glands of the lids, lacrimal apparatus, skin; (2) the hands and gloves of the surgeons, assistant, and nurses; (3) droplet infection through the masks of the participants; (4) dust-borne organisms.

This paper, as indicated by the title, does not purport to deal with any of the first three sources, but does attempt to study the fourth route of infection and to point out possible measures that may be instituted to combat contamination of this nature.

For a better understanding of the various stages through which the instruments pass in these experiments, it might be well to note the procedure formerly practiced in our operating rooms. The towels and dressings were sterilized in the usual steam sterilizers. They were then laid upon tables and covered in the usual manner until ready for use. The instruments were first placed in two porcelain dishes, approximately 8 in. long by 5 in. wide, filled with solution No. 4 to a depth of about 1 in. They were allowed to remain there for from 5 to 15 minutes, after which they were passed through a water bath in a similar porcelain dish. No particular effort was made to cover any of these vessels. Following the water bath, the instruments were laid on towels, from the sterilizer, where excess water was removed, the towels, of course, becoming more or less damp as the last ones were dried. They were then placed upon the operating table.

For the purpose of these experiments, instruments of all sorts were removed at all stages of the procedure, as well as from the operating tables, at the close of a number of operations, and tested by immersion in sterile broth cultures. Care was taken not to open and close scissors, needleholders, clamps, and like instruments when introduced into the bactericide, as it was felt that this precaution would often be omitted by the nurses under the pressure of heavy schedules. It may be noted here that, despite this omission, all instruments were found sterile when tested directly upon removal from this solution.

In the first of these five experiments, all shown in table 1, four instruments, taken directly from the germicide, were cultured. In the second, four more were tested upon removal from the water bath, which had stood for some time uncovered on the preparations table. The cultures

from the first four were all negative after 96 hours. Those from the second four were all positive after 24 hours, definitely showing contamination of the water bath. In the third experiment, the water bath was poured immediately before use and thereafter kept constantly covered. Four instruments cultured upon removal from this bath gave negative results after 96 hours. The fourth experiment shows the results obtained from the tests run upon

profusion on all plates exposed in the operating room from time to time, indicating air-borne organisms as the source of these contaminations.

It would seem from these results, with 36.23 percent of instruments prepared for operation contaminated even after great care concerning the protection of the water bath had been adopted, that the procedure followed in our operating rooms, at least, was inadequate. And the

TABLE 1
COMPARATIVE TESTS MADE UNDER OPERATING-ROOM CONDITIONS

	Number of Instruments	Hours Cultured 24 48 96	Percent Positive

Experiment 5 Instruments cultured from wet towels	5 1 1	- - - + + + - - +	29.60

instruments taken from dry towels, four on one day and 3 on another. From these seven instruments, four cultures remained negative throughout, two were positive in 24 hours, while one was contaminated after 96 hours. In the fifth experiment, seven more instruments were tested upon removal from wet towels, again four on one day and three upon another. Here, five were negative after 96 hours, one was positive in 24 hours, and one at the 96-hour inspection. It is of interest to note that the predominating organism in all positive cultures was the *Bacillus subtilis*, which also appeared in

probabilities are that much the same, or worse, prevail in most institutions. Certainly the indications are that dust-borne organisms have been playing a large part in the contamination of water bath, towels, and instruments. What, then, can be done to reduce the number of such infections? The answer must lie along the line of air sterilization, or, at least, of protection from atmospheric dust. Our hospitals have been woefully slow to put measures directed toward air sterilization into practice, although the benefits of such procedures are well recognized, and have been employed for some time by com-

mercial houses all over the country. Sterilization of the air has been found highly practical and of the utmost economic benefit in canneries, packing houses, and the like. Where the balance sheet is affected, a remedy has been sought and the means found to put that remedy into practice. Where human happiness is at stake, the means has, as yet, not been

so recovered have made very powerful exotoxins which (in one instance) have killed a rabbit in two minutes."

Here, again, in this connection, it is interesting to note that in those infections occurring in our operating rooms last summer and fall, and also one in April of this year, from which cultures were made, large, gram-positive, motile, spore-form-

found to correct the evil, except in a very limited number of instances.

Dr. Deryl Hart,⁴ writing from the Department of Surgery of Duke University Medical School and Hospital, upon "Sterilization of the air in the operating room with bactericidal radiation," reported upon results obtained in 132 extra-pleural thoracoplasties done under sterile lamps. He found that infection, mortality, and postoperative complications were reduced by half. It is his opinion that contamination of the air can be eliminated almost completely by means of bactericidal radiation. Dr. David T. Smith,⁴ from the same department, in discussing Hart's paper, stated, concerning bacteria recovered from the plates exposed in the operating room: "I would not have believed that these were pathogenic bacteria . . . had it not been that organisms

ing organisms, probably hay bacillus, were recovered, similar to those found in the experiments previously reported.

At present, efforts to sterilize the air are directed largely toward direct action on the air and its dust content by the use, either of so-called sterile lamps or by various bactericidal solutions sprayed into the air. In addition, the effectiveness of either method can be enhanced by the application of oil solutions to blankets, cotton sheets, and floors.

Sterile lamps have been developed extensively and are in use commercially at the present time on a somewhat comprehensive scale. Figure 1, taken from a report of the Westinghouse Corporation of experiments conducted by their laboratories upon air sterilization by sterile lamps, gives a rather startling representation of the effect of these lamps upon the

bacterial content of the air of operating rooms during the course of a busy day. From this graph, it will be seen that the bacterial count, though low at first, while the room was unoccupied, rose enormously during preparation for operation, then fell again almost to its undisturbed state during irradiation, despite continued activity, eventually rising to a still greater height when irradiation was discontinued, although activity in the room remained high, only falling once more to the original condition after several hours of vacancy.

In using sterile lamps, two practices may be employed: (1) The field of operation, tables, and other appurtenances may be subjected to the direct rays from the lamps; or (2) All the air supplying the rooms may be drawn in through conduits over large batteries of sterile lamps, as shown in figure 2, taken from another bulletin of the Westinghouse Corporation. The direct rays from the lamps are of such a nature that they cannot be allowed to fall directly upon the operative field in the case of an eye operation, nor can the surgeons operate under them without protective garments and masks. In addition, the heat generated by a sufficient number of lamps for the purpose would often make them unbearable without air conditioning. The second method of application may be satisfactory, provided ample air conditioning can be secured, as otherwise the heat generated would again be an insurmountable obstacle on many a summer day, when operations must be performed.

The second procedure, that of spraying the air with various bactericidal solutions, gives promise of becoming a practical and satisfactory method under certain conditions. Many investigators are working on this problem at the present time, as the medical personnel of all branches of the Armed Forces are interested be-

cause of its bearing upon the reduction of cross infection in barracks and other places where large groups of men are housed in crowded quarters.

In this country, Dr. O. H. Robertson,⁵ of the University of Chicago, has been active in these investigations. He, with his associates, working with propylene

Fig. 2 (Post). Diagram showing how air supplying operating rooms may be drawn through conduits over large batteries of sterile lamps (by permission Westinghouse Lamp Division).

and, more extensively, with triethylene glycol vapor, have shown that 1 c.c. of this substance in 10,000 cu. ft. of air, is lethal to pneumococci, streptococci, and influenza virus previously injected into the air; that, in this concentration, it cannot be detected and is noninjurious to individuals, even after long exposure to its effects. It is most potent, however, at rather high humidity. For instance, the influenza virus survived less than 24 hours at a humidity of 80 to 90 percent, whereas in dry air 25 to 30 percent were recovered after 36 hours.

For its satisfactory use, it is necessary to have control mechanisms and vaporizers. Drs. Puck, Wise, and Robertson⁶ have developed a most ingenious, though simple, device, in which control depends

upon variations in the intensity of a beam of light reflected from a polished brass band onto a photoelectric cell, the amount of condensation upon the metallic surface cutting down the stimulus to the cell as the vapor concentration increases in the air, and, on the contrary, permitting greater intensity as the vapor content diminishes. The photoelectric cell may be connected to a vaporizer that can be set up to spray vapor into the air, as called for. Several types of vaporizers have been developed, one by the Research Corporation of New York, and one by Biggs and Jennings⁷ of the Technical Institute of Northwestern University.

It is obvious that this method of air sterilization, as well as that by sterile lamps, generates heat and humidity and, for accurate control of the vapor content in the air, requires a closed room, which, in turn, necessitates a satisfactory system of air conditioning for its practical application.

As suggested previously, using either type of air sterilization, the results can be greatly improved by oiling the blankets and sheets. Harwood, Powney, and Edwards,⁸ writing in the *British Medical Journal* for May, 1944, have given detailed instructions for the attainment of satisfactory oiling of these articles. After washing, blankets may be treated in the hospital laundry, using "Fixanol C," a cation-active agent, to deposit upon them a 4.8-percent concentration of oil. Cotton sheets may be treated in a similar way, followed by "Teepol," an anion-active agent, leaving a concentration of 6.7 percent of oil upon these fabrics. Although the results of such treatment cannot be detected by observation or touch, they nevertheless, remain effective for a number of months.

All observers have attributed much of the air pollution to disturbance of the dust upon the floors. It is, therefore, of

the utmost importance that some method to hold that dust be instituted. Dr. O. H. Robertson and associates⁵ have suggested that pale paraffin oil be used, which will hold dust for many weeks. On tiled floors it may, however, become slippery. Should such be the case, a solution of urea (5 percent), ninol (3 percent), and rocall (0.9 percent) may be substituted very effectively, but must be renewed every few days.

Under present circumstances, air conditioning by either sterile lamps or triethylene glycol vapor is quite impractical in most hospitals, both because of the expense involved and the difficulty in procurement of the necessary equipment. There are, however, a few simple procedures which the author wishes to bring to your attention that are of value in combating infections from these dust-borne organisms. In the first place, all towels, dressings, solutions, and instruments should be protected from dust by sterile covers as much as possible. This is obvious. The second suggestion is to recommend the practice of dipping all instruments which actually enter the aqueous or vitreous chambers into boiling water, or sterilizing solution, for a few seconds immediately before use. Such procedures have been employed sporadically for many years, but I know of no experimental studies that have been made definitively to determine their value. The writer wishes, therefore, to report here a number of experiments which have been carried out with this purpose in mind.

It is well here to point out that this work could not have been done without the assistance and many valuable suggestions of Mr. William Moor, the coauthor of the third paper on this subject. The cultures reported have been taken and read by both of us, working together. The experiments reported earlier in this paper may be considered as belonging to the

first group, and these to the second group.

In this second group, shown in table 2, 18 instruments of various types were taken as a control from eight different operating tables, following their use in operations of one sort or another upon the eye. Cultures taken from these were found positive in 14 out of the total number tested, indicating 77.77 percent contamination at the close of operation. In

which was to be introduced inside the anterior, posterior, or vitreous chamber of the eyeball into various solutions for varying periods of time, immediately before their use in the operation.

In the first of these studies, the instruments were dipped in water immediately after boiling had ceased. One instrument dipped for 1 second gave a positive culture after 24 hours; 1 dipped for 1½

TABLE 2

RESULTS OF EXPERIMENTS CARRIED OUT UPON INSTRUMENTS TAKEN FROM IDENTICAL OPERATING TABLES

Instruments Cultured	Dipping Time seconds	Number of Instruments	Hours Cultured 24 48 96	Percent Positive
Control experiment from postoperative tables	0 0	14 4	+ + + - - -	77.77
Experiment 1 After dipping in water just below boiling point	1 1.5 2 2	1 1 2 2	+ + + - + + - - + - - -	100 100 50
Experiment 2 After dipping in boiling water	1 1 2.5 2.5	1 6 1 7	- - + - - - - - + - - -	14.28 12.5
Experiment 3 After dipping in zephiran 1/3000	2.5 2.5	2 31	- - + - - -	6.66

considering this high percentage, it should be realized that these instruments have been subject to contamination by all four routes previously indicated. It would appear reasonable that if a large proportion of similar instruments taken from these same tables could be sterilized by any method, the procedure employed should be equally, or even more highly, successful in sterilizing those contaminated by dust-borne organisms alone.

The following experiments, reported in table 2, have, therefore, been carried out upon instruments taken from the identical operating tables reported in the foregoing control experiment. The same principle was employed in each instance; namely, dipping the end of the instrument

seconds was positive after 48 hours; but of 4 dipped for 2 seconds, only 2 were positive after 96 hours.

In the second experiment, boiling water was employed. The results, as shown in table 2, were that, of 7 instruments dipped for 1 second, only 1 culture was positive after 96 hours, and of 8 dipped for 2½ seconds, 1 alone gave a positive culture after 96 hours.

It would appear from these experiments that both procedures reduce the percentage of contamination to a very large extent and are well worthy of adoption. The boiling water at one's elbow is, however, somewhat of a nuisance, and on warm days definitely increases the heat and humidity. A solution was sought,

therefore, which might be substituted for boiling water; one that would cleanse the instruments without injury to them, or to the eye being operated upon, should occasional droplets be introduced into the eye in the manipulation. In general, the synthetic detergents seemed well suited for such a purpose. Of the 2,000, or more, of these which have been produced, zephiran is one of the most extensively studied and most satisfactory in action.

the eyeball upon instruments, none have thus far been brought to my attention, even though due to error a 1/300 concentration was used for about one month.

As previously noted in experiment 2, of the first group, the water bath was highly susceptible to contamination. The satisfactory results obtained by dipping the instruments into the zephiran bath suggested that a similar solution might be used for the removal of the original

Certainly, its effect upon ocular tissue is well understood. It belongs to the cationic group, all of which are very effective inhibitors of bacterial metabolism at 1/3,000 concentration, and some even at a much greater dilution.

In the third of this group of experiments, therefore, an aqueous solution of zephiran 1/3,000 was substituted for the boiling water. The results, as shown in table 2, experiment 3, were most satisfactory. Of 33 instruments dipped in this solution for 2½ seconds, only 2 cultures were contaminated after 96 hours, that is, 6.66 percent, a considerably lower figure than that obtained in either of the two previous experiments with water baths. Furthermore, though all members of the staff have been asked to watch carefully for any deleterious effects traceable to droplets of this solution being carried into

germicide No. 4 from the instruments, instead of the water bath. A fourth experiment, shown in table 3, was, therefore, carried out, to determine the time that an aqueous solution of zephiran 1/3,000 concentration would remain sterile during exposure to the air in a tray similar to that used for the water bath. Five minims of this solution was removed from the tray at intervals, as shown in the graph, and dropped into culture tubes. As long as the experiment continued, five hours, no positive results were obtained.

To reinforce the findings of this procedure, five instruments were cultured which had just been sterilized by immersion for five minutes in the germicide No. 4, and then washed off in the zephiran bath, as shown in experiment 5, table 3, allowing the bath to stand exposed for 30 minutes. Five more instruments were

similarly treated, after the bath had stood exposed for 90 minutes. As was to be expected, in both instances the cultures remained sterile.

SUMMARY

The conclusions to be drawn from the experiments reported here are, therefore:

1. Keep covers on all solutions, towels, instruments, and the like, as much as possible.

2. Substitute an aqueous solution of zephiran, or some similar detergent, for the water bath.

3. Dip all instruments that are actually to enter the eyeball into a suitable sterilizing solution, or boiling water, for at

least $2\frac{1}{2}$ seconds immediately before use.

4. Install, as soon as practicable, some method for air sterilization in the operating room.

5. Treat all blankets and sheets with some type of oil solution.

6. Treat the floor of the operating room with some type of dust-allaying preparation.

In closing, it may be of interest to note that since these investigations started, approximately 600 intraocular operations have been performed, yet only one instance of infection has occurred, and in this case the precaution of dipping the instruments immediately before use, through a misunderstanding, was not observed.

DISCUSSION

DR. WILLIAM M. JAMES (St. Louis): Dr. Post has been interested for many years in the sterilization of the sharp instruments used in ophthalmic surgery. It is fitting that he should call our attention to the dust-borne infections and at the same time suggest methods for their control.

The value of sterile lamp irradiation and of spraying the air with triethylene vapor has been reported and will be used when air conditioning again becomes available.

The results of cultures taken by Dr. Post and Mr. Moor from surgical instruments show that the instruments were being contaminated in the uncovered

water bath. The incidence was 36 percent, before use and 77 percent after use. By dipping the instruments in either boiling water or in zephiran 1/3,000 the percentage of positive cultures was reduced to 12 percent and to 6 percent. The advantage of using an aqueous solution zephiran 1/3,000 in place of the usual water bath in sterilizing sharp instruments is shown in table 3.

Dr. Post has told me that there has been some rusting of the instruments following the use of zephiran in the water bath. The Alba Company, the producers of zephiran, state that this factor may be controlled by using 0.5-percent sodium nitrite in the zephiran solution.

DR. WILLIAM H. CRISP (Denver): I suppose everything we can do to improve the sterilization of instruments is not only justified but demanded. However, I wonder whether we do not underestimate the capacity of nature for eliminating danger from the more remote sources of infection. I have never seen anything to lead me to suppose that I picked up an infection from the air of a well-conducted operating room. Over most of my professional career, my sterilization of instruments has been done by simple immersion not in actively boiling water, but in water which has been boiling just before I use it and under which the source of heat has been cut off temporarily so that I shall not scald my hands in the process which I use. For the cataract knife, the Graefe knife, the keratome, or any other knife, I simply hold the knife for 16 to 20 seconds in the water under which the gas has just been turned off so that it is at boiling temperature but not actually boiling. I use all the rest of my instruments in the same water at boiling temperature, but no longer actively boiling, for death of bacteria comes below the boiling point. Most killing or cooking processes are accomplished well below the boiling point, so that I am not afraid of the fact that I have had the gas turned off. I believe that nearly all the inflammatory processes which we see after operation in an eye are due to some variation in surgical technique rather than to active infection. I believe the slow inflammatory processes, especially, do not arise mostly from actual infection.

If you have a foreign body on the cornea, that foreign body tends to favor bacterial development. As soon as the foreign body is removed, unless some process of infection has gone very far, the eye usually reacts very kindly toward it. The point being that any foreign material,

or any trauma, will favor bacterial infection; but that bacterial infection very generally does not develop unless the tissues have been traumatized in some unfortunate way. I do not believe any operator on the eye ever performs two successive operations in exactly the same way. There are slight variations in technique. Some of these depend upon slight variations in the anatomy of the individual eye, and I believe that the neatest possible surgery, with avoidance of undue trauma to the tissues, plays a much more important part than our extreme efforts to avoid infection. I am reminded of something I was told about the older Pagenstecher, who many years ago, before sterilization was given as much attention as it is today, always passed the cataract knife between his lips just before making the incision. He said this action made the knife go through more easily; and I do not suppose that he had a greater proportion of cases of infection after his cataract operations than most of us at present. The point here is that, under favorable conditions, the eye is extremely resistant to the threat of infection. For one thing, we have the rapid initial flow of the aqueous, which reduces the basis for bacterial development. Our main salvation lies in the simplest and most straight forward possible surgery, with proper respect to the exact anatomy of the eye of the patient we are dealing with. However, I appreciate that Dr. Post has been doing some excellent scientific work in this direction, and I very much respect what he has done.

DR. FRANCIS HEED ADLER (Philadelphia): I should like to call attention to a factor which will become more prevalent in our operating rooms, and that is the dust-borne infections due to air conditioning. In 1937, our new operating room was opened. We had no trouble from

infections until the first hot week of the summer, when the air-conditioning system was turned on. In that week I had two intraocular infections. Cultures of one of the eyes showed colonies of *Bacillus subtilis* and the contamination was traced to the air in the room, which was heavily laden with the hay bacillus. It was discovered that the air which came through the system was passing through a chamber loaded with dust and hay bacilli. Dr. Wells and Dr. Stokes have solved our problem by spraying the ducts through which the air is pumped with triethyl-glycol; since then we have had no further infections.

DR. ARTHUR M. YUDKIN, (New Haven): It is evident from the investigation of Post that dust-borne infection is of great importance in ophthalmic surgery. Although I have not encountered many postoperative infections of the orbital tissue in muscle operations, cataract extractions, operations for glaucoma, or detachment of the retina, I know that some ophthalmic surgeons have been concerned about the frequency of postoperative infections. From 1939 to 1945, when it was most difficult to obtain well-trained assistants in the operating room and the operating teams were overworked, we were free from postoperative infections. It was not unusual for an eye operation to follow an abdominal operation, yet with ordinary care no infections of the ocular tissue were observed.

It is a miracle why more infections are not encountered postoperatively in ophthalmic surgery, for the conjunctiva cannot be sterilized properly, and it is extremely difficult to free the air from air-borne infection. We observe the same operating room technique employed by the general surgeon. The noncutting instruments, towels, gowns, basins, dropper

bottles, and table covering are autoclaved under pressure. The medication is sterilized by the drug department daily. The cutting instruments are placed in Post's original sterilizing solution for 5 to 10 minutes.

Post's recommendation of a system of lamps to sterilize the air-borne infection is commendable, and I believe the operating room of the future will be air conditioned and constructed so the air can be sterilized. Not only should the floor of the operating room be prepared with a dust-allaying preparation but the whole operating suite should be protected. The clothing of the operator and assistants should also be considered as a source of contamination. I am satisfied that too many precautions cannot be taken to make an operating field free from extraneous infection. It is important that the operating team and the patient be comfortable in this ideally constructed operating suite of the future.

DR. M. HAYWARD POST (closing):

I agree with Dr. Crisp, and realize the truth of his remarks. Our experiments have demonstrated that the eye has a tremendous capacity to fight infection. They show that, though we had 77.77 percent of contamination at the close of operation, yet the hospital records in the past have shown relatively few infections, about one tenth of 1 percent, with approximately 600 intraocular operations performed annually. However, if we can reduce that percentage to nothing, we are making a definite advance. I might also cite in this connection, the experience we had when Colonel Smith demonstrated his intracapsular operation for us on 42 cataracts in one afternoon. During those operations, he smoked no less than four cigars; there were various complications, but no infections.

I attribute the lack of infection at the hands of the older operators to the fact that they were careful not to touch the tips of their instruments, and that they used fewer instruments; consequently, each one could be laid back carefully, so that its tip was not touching anything that might cause contamination.

As to Dr. Adler's remarks, I would say that I have read merely an abstract of my paper. In the complete paper, air sterilization by triethylene glycoll and ultraviolet is discussed, and ways suggested in which they may be used with safety. Much has still to be done on that subject before the answer is known.

NOTES, CASES, INSTRUMENTS

VENOUS PULSATION AS A SYMPTOM OF EARLY GLAUCOMA*

SAMUEL ENGEL, M.D.

San Francisco

The phenomenon of pulsation of the retinal vessels is usually looked upon as only a curiosity without much clinical significance. Arterial pulsation is present in glaucoma at a pressure of about 60 mm. Hg (Schiotz). The artery is compressed in diastole, while the vessel is still able to fill in systole, at which time the arterial pressure is slightly higher than the intraocular pressure. Among medical diseases, arterial pulsation is found in aortic insufficiency as a manifestation of the increased pulse-volume, and in Graves's disease.

Venous pulsation as a physiologic phenomenon can be seen in a considerable number of patients, particularly in children. It is due to the fact that the venous pressure is about equal to the intraocular pressure, and the increased filling of the choroidal arteries in systole raises the intraocular pressure just enough to compress the vein, which dilates again in diastole. The appearance of venous pulsation depends, therefore, on the intraocular pressure and on pressure in the vein. In the majority of patients, it can be brought about by increasing the intraoc-

ular pressure by pressing slightly on the eyeball. When the pressure is further increased, venous pulsation may be present even together with arterial pulsation.

Increased intracranial pressure, by compressing the vein in the subarachnoid space surrounding the optic nerve, causes stasis in the retinal veins and so raises the pressure in the veins. Absence of venous pulsation is, therefore, an early sign of papilledema. Manz (1874) and Laqueur (1877) observed that venous pulsation is usually lacking in "inflammation of the meninges" with marked venous hyperemia of the retina (cited by Leber¹). In neurologic patients suspected of cerebral disease, I am inclined to regard the presence of venous pulsation as a sign which makes increased intracranial tension highly improbable, a fact also stressed by Baurmann.²

While examining several patients for refraction or because of slight discomfort, I was impressed to observe marked venous pulsation in one eye which was not, or only to a lesser degree, present in the other eye. The pulsation had a slightly different character from the type usually seen. It was more "jumpy;" the constriction was more marked; and the filling more rapid. When taking the tension of such an eye, I found an increased intraocular pressure in many cases. Physiologic variations in the appearance of the venous pulsation were present, and

*From the Department of Ophthalmology, Stanford University Medical School.

I did not find increased tension in all suspected cases. However, those which showed an increase in tension might have been overlooked if my attention had not been attracted by the pulse phenomenon.

CASE REPORTS

Short reports of three histories follow:

Case 1. Dr. S. K. D., aged 60 years, came to me in February, 1943, because he felt a slight pain in the right eye when coming from the light into the dark, also after lighting a match in the dark. Examination showed vision to be: O.D., with a +1.25D. sph., 20/15; O.S., with a +1.50D. sph., 20/25. The left eye had always been the poorer eye. The pupil of the right eye was slightly larger than that of the left; the anterior chamber deep. There were two tiny precipitates on Descemet's membrane. The discs were normal, but showed a marked venous pulsation, with the aforescribed "jumping" characteristics in the right eye. There was a slight venous pulsation in the left eye. The intraocular pressure was 40 mm. Hg (Schiotz) in the right eye; 20 mm. in the left.

A diagnosis of serous iridocyclitis, with increased intraocular pressure, was made, and the right eye treated with mild mydriatic drops. The tension dropped slowly to 23 mm., and the pulse phenomenon decreased in intensity until it was the same as in the left eye.

When the patient had a similar attack in October, 1943, the degree of venous pulsation made it possible to assume approximately a rise or fall in tension, which was confirmed by the tonometer.

Case 2. Mr. A. W. E., aged 72 years, was seen in October, 1944, for refraction. Examination disclosed vision to be: O.D., with a -1.00D. sph. \subset 1.50D. cyl. ax. 15°, 20/40; O.S., with a 1.25D. cyl. ax. 165°, 20/15. (Vision in the right eye

had always been impaired.) The iris of the right eye showed a small peripheral coloboma at the 5-o'clock position and some fine posterior pigment synechiae. Gonioscopy revealed that a small tissue stump had been left peripheral to the coloboma and that there were anterior peripheral synechiae on both sides of the coloboma. As the patient had never had his eyes operated on, this condition was assumed to be a coloboma after early inflammation of the iris.

The pupils reacted to light, although slightly irregularly in the right eye. The discs were normal. The vessels of the right eye showed slight bending, which could have been regarded as within physiologic limits. But the central vein of the right eye had a strongly accentuated pulsation, whereas the pulsation in the left eye was just visible. The tonometer registered a tension of 33 mm. Hg (Schiotz) in the right eye; 23 mm., in the left.

Under treatment (2-percent solution of pilocarpine), the tension of the right eye dropped to normal, and the difference of pulsation between the two eyes disappeared.

Case 3. Mr. W. L., aged 42 years, on a visit to California, came to see me in October, 1945. The day before he had had an attack of cloudiness over the right eye after an afternoon's exposure to sunlight. For the past year, he had experienced similar attacks, but of lesser degree, two or three times monthly. Ten years before, holelike changes of oval form in both maculas (from solar radiation?) had been observed. This had impaired his vision as follows: O.D., with a -4.00D. sph. \subset -0.50D. cyl. ax. 90°, 20/25; O.S., with a -0.50D. cyl. ax. 90°, 20/30.

The right eye, whose anterior chamber was deep, showed neither corneal edema nor precipitates. Both discs were normal. A venous pulsation, "jumpy" in char-

acter, corresponded to a tension of 42 mm. Hg (Schiotz), which decreased to 26 mm. under pilocarpine treatment. Tension in the left eye had always been normal.

On a search through the literature only one reference was found, that of Troncoso, who mentioned, as an ophthalmoscopic symptom of glaucoma, that: "the veins frequently show spontaneous pul-

sation." It would, therefore, seem worthwhile to draw attention to the fact that a *difference* of venous pulsation in the two eyes, particularly if "jumpy" in character, may be a sign of an early glaucoma that does not yet show marked clinical symptoms and should induce the physician, if for no other reason, to test ocular tension.

CORNEAL INSULT FROM PODOPHYLLIN

ROBERT S. ROSNER, M.D.
Cleveland

Ophthalmologists must constantly advise doctors against treating skin conditions around the eye as they would elsewhere on the body. The following case points out that doctors have yet to learn this simple dictum.

A practitioner of medicine treated a patient for "warts around the left eye" with a 25-percent solution of oleoresin podophyllin in mineral oil. He stated that this medication was used for the removal of warts in other regions of the body with good results.

REPORT OF A CASE

A white man aged 52 years, in good general health except for a rectal condition for which he consulted his doctor, was advised by the same doctor to have some warts removed from the region of his left eye for cosmetic reasons. The patient was given a prescription for 25-percent oleoresin podophyllin in mineral

oil to be applied nightly with a glass rod to the affected parts. On January 27, 1946, the patient applied this medication to the areas as instructed. No ill effects resulted from the first application. The following night his son applied the medicine to the parts with a glass rod. The patient went to bed soon after, and, during the night, his nose "ran like water," and his left eye smarted and itched. He said that he had not been conscious of any seepage of the medication into the eye but felt that this must have occurred while he slept. Twice during that night he awakened because of some discomfort around the left eye. The next morning the left eye was "all red and puffed up." Some discomfort was present, but no severe pain. He was able to stay on his job by squinting and keeping the left eye closed. When the eye was opened, he felt some pain. He consulted the practitioner on January 29th, because the pain grew progressively worse. An analgesic ointment was instilled, and the eye bandaged. The doctor instilled more ointment on the following morning. The patient then became aware that vision in the involved eye was

extremely blurred, although the pain had somewhat abated. He was sent to the writer for consultation on January 31, 1946.

OPHTHALMOLOGIC EXAMINATION

Visual acuity was 6/6 in the right eye, and 1/60 in the left eye. On the skin of the temporal half of the lower lid of the left eye were multiple small papillomatous growths; a few were on the upper lid also. There was dryness and excoriation of the skin around the outer canthus. Moderate photophobia was present. The bulbar and palpebral conjunctivas were congested and edematous. Ciliary venous congestion was marked. There were considerable lacrimation and some bhepharospasm, which were somewhat relieved by the instillation of a 0.5-percent solution of pontocaine. A 2-percent solution of fluorescein was applied, followed by another drop of pontocaine. An irregular rounded corneal ulcer took the stain. This ulcerated area, located directly at the center of the cornea, was about 4 mm. in its widest diameter. There were also two other tiny ulcers near the limbus, one at the 11-o'clock, and the other at the 5-o'clock position. The entire corneal epithelium was strikingly hazy and lusterless (see figure 1).

Slitlamp examination. The edema of the epithelium was seen chiefly by retroillumination. It had the appearance of tiny globules of varying sizes. The ulcer, disciform in appearance, was superficial, amounting only to a loss of surface epithelium. No erosions were present in Bowman's zone, and there was no corneal vascularization. The vascular plexuses at the limbus were greatly congested. Many tiny, rounded spots of infiltration in the corneal stroma extended down to Descemet's zone. The most remarkable finding was that Descemet's membrane was wrinkled throughout the

entire posterior corneal surface. No keratic precipitates were present. There was a one-plus aqueous ray, but it was assumed that this was caused by diffraction of light by the translucent and hazy cornea. Even with the use of a high-power lens, no cells were seen in the anterior

Fig. 1 (Rosner). Corneal lesion as the result of the use of oleoresin podophyllin in the region of the eye.

chamber. However, it was difficult to penetrate the corneal haze. The iris showed no involvement.

Ophthalmoscopic examination. Only a red reflex could be obtained in the left eye. No details whatever were visible. The right eye was entirely normal. A 3-percent solution of homatropine was instilled into the left eye. This was followed by the application of holocaine-epinephrine ointment and an eye pad. The patient was observed daily. On the third day, the ulcer had healed, and the area did not take the fluorescein stain. Vision had improved to 4/60. Although the pain had subsided

completely, one could not obtain a view of the fundus. Descemet's membrane was still wrinkled in a peculiar wire-screen or checker-board fashion which was most noticeable near the center of the cornea. The corneal periphery was clearing well. Even though the anterior chamber was not entirely clear, there was no aqueous flare. High-power examination failed to reveal any cells. Treatment consisted of frequent instillations of sterile olive oil. The eye pad was removed. On February 8th, the cornea had cleared sufficiently for the patient to be able to read the 6/9 line. However, even though they were fading, the criss-cross folds in Descemet's membrane could still be seen.

OUTCOME

Not until one month after the onset of this disturbance did the eye become totally quiet. Grossly, one could see a faint, nebulous scar at the center of the cornea.

Vision in the left eye was corrected to 6/7.5-2. Slitlamp examination revealed that the wrinkles in Descemet's membrane had disappeared completely. The nebulous region was carefully studied. It consisted of extremely fine, silvery dots and spots scattered throughout the substantia propria of the cornea. Bowman's and Descemet's zones were not involved in this process. A good fundus view was obtained, and the fundus was entirely normal.

CONCLUSION

A case of corneal insult from oleoresin podophyllin has been presented. One cannot help but marvel at the recuperative powers of the cornea. Despite this fact, ophthalmologists should warn the general practitioner of medicine to treat skin conditions around the eye with utmost caution.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

November 5, 1945

DR. PERCY FRIDENBERG, *presiding*

IONTOPHORESIS IN OPHTHALMOLOGY

DR. LUDWIG VON SALLMANN presented a paper on this subject during the instructional hour.

GENERAL ANESTHESIA IN OPHTHALMIC SURGERY

DR. MORRIS BIEN gave a report on this subject which has been published in this Journal (September, 1946).

Discussion. Dr. James W. Smith said that some slips in technique are seen in the general hospital which nullify the anesthetist's efforts. Preoperative orders for children are not always followed, and the operation may be interrupted by vomiting of orange juice or food given before operation, usually by a comrade. He said that he has observed marked cyanosis in children after operation when the nurses failed to remove the endotracheal airway. When pentothal anesthesia is employed, adequate local anesthesia must be used because there may be pain, especially in muscle surgery.

Dr. Joseph J. Fried described a case in which pentothal was used for an iridectomy. When the iris was grasped, the patient sat up and sneezed; this was repeated after a few minutes wait. Another patient, given pentothal for an enucleation, remained unconscious for three days. The diagnosis was respiratory depression from the anesthesia. Within a few days, a fatal hypostatic pneumonia developed.

Dr. Benjamin Esterman inquired about the dosage of atropine as premedication for ether anesthesia.

Dr. Bien said that he has experienced the same difficulties which Dr. Smith described. He avoids very deep anesthesia in children, tries to anticipate the end of the operation, and stops the anesthesia early so that, by the time the eye is dressed, the reflexes are returning and the airway can be removed in the operating room.

The average dose of atropine for an adult is 1/150 gr. However, the dose varies with the patient. A 16-year-old patient would receive 1/200 gr. together with 1/8 gr. of morphine.

The best time for administration is one hour before operation when given in conjunction with an opiate, and one-half hour before if given alone.

LOCAL ANESTHESIA IN OPHTHALMOLOGY

DR. WALTER S. ATKINSON attributes many operative accidents to forcible contraction of the orbicularis or to failure of the patient to hold well because of incomplete anesthesia. Many cases of vitreous loss are due to poor anesthesia and, if more than one percent of uncomplicated cases lose vitreous, the anesthesia procedure should be checked.

A patient's confidence is an important factor which sedatives aid in achieving, but sometimes sedatives produce excitement, nausea, or vomiting. Administering them the night before operation will indicate the patients who react adversely. For preoperative use, phenobarbital or pentobarbital, 1.5 gr. or more, with aspirin, 5 gr. (the latter apparently has a synergistic action), is effective. Tetracaine (pontocaine) 0.5 percent is the most suitable of the surface anesthetics. Procaine (2 percent with 1 drop of epinephrine 1:10,000 to 5 c.c.) is also effective. The epinephrine is raised to 4 drops for

retrobulbar anesthesia when it is desirable to lower intraocular pressure. A luer-lock syringe is the most satisfactory type. Needles recommended are: no. 27 (12.5 mm.) for subcutaneous use; no. 25 (2 cm.) for akinesia and deeper subcutaneous injection; and no. 22 (3.5 cm.) for retrobulbar and deep injection.

The O'Brien lid block seems more efficient than the Van Lint. In performing this, have the patient open his mouth to permit identification of the condyloid process, introduce the needle almost to it, inject a few drops, advance to the process and inject 2 to 3 c.c. If akinesia does not take place in a few minutes, another injection is indicated.

It is advisable to produce a dermal wheal prior to retrobulbar injection which should be done with a 3.5 cm. needle having a rounded point. If the patient looks up and away from the site of injection, the fascial connection of the muscles will be drawn away. As long as the needle is within the muscle cone, anesthesia will be satisfactory because the solution diffuses throughout the fatty tissue. For operation on the globe, 1 to 1.5 c.c. is injected, and 3 c.c. for enucleation or muscle operations. This will block the sensory nerves and produce paresis of the rectus muscles which reduces the likelihood of squeezing. The anterior chamber will be deeper; the lens capsule will be looser; and the possibility of vitreous loss will be diminished. Concurrent instillation anesthesia is required since only the conjunctiva about the cornea is anesthetized. Retrobulbar anesthesia is also useful in lowering pressure and relieving pain in acute glaucoma.

For lacrimal sac operations, the infra-trochlear nerve is blocked by inserting the needle to a depth of 3 cm. at the upper-nasal angle of the orbit. Another 0.5 c.c. is injected at the supra-orbital notch. To produce anesthesia of the duct and lower sac, the infra-orbital nerve is blocked by

inserting the needle in the canal, which is 1 cm. from the ala of the nose, and injecting 1 to 2 c.c. If there is no foramen, or if it is missed, the injection is made at the infra-orbital fissure.

Tumors of the lid are removed under infiltration anesthesia except in cases when they are so large that they require block anesthesia. This is produced by injecting along the orbital margin, carrying the needle close to the bone to beyond the horizontal borders of the lid.

Discussion. Dr. Max Kimbrig described one case in which the pupils dilated after the use of tetracaine. He thought there had been some error made and reinstalled the drug at a later date with pupillary dilatation again taking place.

Dr. Harvey Thorpe said that occasionally patients will be given tetracaine for treatment of corneal ulcers or other conditions. Sometimes the eye becomes sensitive to this drug, and a corneal ulcer develops which takes many weeks to heal. He considers the retrobulbar injection of novocain of great value as it softens the globe and minimizes vitreous loss. The needle should be examined before use. A damaged point may tear an orbital venule and result in retrobulbar hemorrhage. Placing the finger between the globe and lower orbital margin, thereby pushing the eye upward, facilitates the passage of the needle behind the globe.

Dr. Atkinson stated he had never seen a case of dilatation of the pupil with tetracaine.

PHARMACOLOGY OF OPHTHALMIC DRUGS

DR. WALTER MODELL stated that the conjunctiva are excellent absorbing surfaces. Lowering the surface tension speeds their absorption. The wetting agents or detergents which accomplish this often are quite irritating, but the aerosols and zephiran, in proper concentration, can be used safely. The closer the

osmotic tension to isotonicity with the tears, the more rapid the absorption. Tables indicate the amount of salt required for various drugs. Most ophthalmic drugs can be buffered to slight alkalinity at which they are absorbed best by the conjunctiva. The closer alkalinity is to pH 7.5, the less is the irritation.

The sulfonamides and penicillin have resulted in new standards of antibacterial effectiveness. A chemical antiseptic, by definition, retards the development of disease-producing bacteria in vitro, but the in-vitro characteristics have no bearing at all on an antiseptic's usefulness in treating infections on the surface of the eye or in the body, and some interfere with the body's normal anti-infective actions. They may be mutually antagonistic with the lysozyme of the tears, vitiating the antibacterial properties of each other. In general, sterile wounds heal more rapidly if antiseptics are not applied and, in infected wounds, strong chemicals seem to retard the eradication of bacteria. It is doubtful if local infections in the eye are exceptions to this rule.

Experience has shown that the local use of sulfonamides is not as effective as originally believed. All evidence indicates that they work from the interior of the cell and not as surface-acting materials.

Penicillin is surface active and well-absorbed by the eye. It is effective by injection and orally but about five times as much must be taken by mouth for effects equivalent to those produced by intramuscular injection. The blood level must be maintained continuously as peaks represent wasted penicillin.

Ophthalmology has, perhaps longer than any other branch of medicine, made use of drugs acting on the vegetative nervous system. The choline group is one of the recent parasympathetic-affecting additions to this list of drugs. Their action in the eye simulates stimulation of the

oculomotor nerve which normally functions by elaboration at the nerve ending of acetylcholine which in turn is destroyed by cholinesterase. Acetylcholine is too quickly destroyed to be useful clinically. Mecholyl, its betamethyl derivative, is much more slowly destroyed and is clinically valuable. Doryl, called carbachol for ophthalmic use, is carbaminoylcholine, and is not destroyed at all by esterase. Its absorption, when instilled in the eye, is enhanced by a wetting agent, for which zephiran is usually recommended.

Physostigmine and prostigmine produce their parasympathetic effect by destroying esterase and permitting the accumulation of the acetylcholine. When administered together, they similarly protect mecholyl.

A new derivative of carbachol, called dibutoline, introduced by Swan, has an increased surface activity and is well-absorbed by the eye. Surprisingly, its action is similar to atropine, being a mydriatic and a profoundly rapid acting cycloplegic. It is antiseptic, as are all wetting agents. The best explanation for its reversal in action is that it is actually inactive but that it is so similar, chemically, to acetylcholine that the body does not discriminate between the two. If enough is present, it displaces the normally formed acetylcholine and prevents its action.

Discussion. Dr. Fredrick H. Theodore said that he thought Dr. Modell felt that the sulfa drugs were not effective when applied locally to the eyes. He described well-controlled cases which showed the contrary: (1) An occlusion body conjunctivitis that had not been treated for one month. Local sulfa treatment resulted in complete disappearance of clinical symptoms and signs in three days. (2) An acute staphylococcus conjunctivitis which cleared up with the local use of sulfonamides alone. Dr. Theodore also remarked on the great frequency of aller-

gic reactions produced by penicillin ointment.

Dr. Adolph Posner pointed out that pilocarpine has been a standby for many years. Only recently have the choline derivatives become popular. With Dr. Mark Schoenberg he developed some criteria regarding their use. It seemed to him that prostigmine or doryl are no better than pilocarpine and probably less reliable in chronic glaucoma. Their effect probably depends on the state of the parasympathetic system at the time of use.

Dr. Modell said he did not question that sulfonamides used locally are effective in the treatment of some infections of the eye. He questioned, however, whether the local use of the drug is superior to adequate oral administration.

Regarding reactions to penicillin, he said that all such reactions may not be due to the penicillin itself. About 50 percent of the parenteral penicillin preparations now on the market have impurities which may be to blame. However, there is reason to believe that, in some cases, pure crystalline penicillin also produces reaction.

Pilocarpine acts to produce parasympathetic effects much like those produced after the administration of physostigmine. It acts directly, however, and not, as does the physostigmine, through an intermediary acetylcholine. Since pilocarpine is more independent in its action than physostigmine, it seems reasonable to suggest that there may be situations in which pilocarpine would produce satisfactory effects while physostigmine or prostigmine would fail.

RECENT PROGRESS IN OPHTHALMIC THERAPY

DR. JAMES W. SMITH said penicillin is the drug of choice, and effects a more rapid cure than the sulfonamides in the

treatment of gonorrheal ophthalmia, penetrating injuries, orbital cellulitis, and ulcerative keratitis. The organisms most sensitive to penicillin are beta-hemolytic streptococci, gonococci, streptococci viridans (alpha), streptococci anhemolyticus (gamma), and some strains of staphylococci.

Penicillin may be applied locally by instillation (500 to 10,000 Ox. u. dissolved in 1 c.c. isotonic sodium chloride or distilled water, pH 7.7), conjunctival pack (20,000 Ox. u. per c.c. concentration), ointment (1,000 Ox. u. per gm.) intramuscularly, intravenously, or orally (calcium-penicillin tablets 20 to 25,000 Ox. u.). Intraocular infections of the anterior segment after penetrating wounds can be treated by withdrawal of 0.25 c.c. of aqueous and replacement by penicillin solution (1,000 Ox. u. per c.c.).

The clinical disorders responding to the sulfonamides are trachoma, inclusion conjunctivitis, lymphogranuloma venereum, gonorrheal ophthalmia, streptococcal corneal ulcer, bacillus pyocyaneus ulcer, erysipelas, impetigo of the lids, and staphylococcal blepharoconjunctivitis.

Sulfathiazole and sulfadiazine penetrate poorly through the cornea. The wetting agents, by lowering interfacial tension, increase the concentration of these drugs in the aqueous humor and make them effective for treating anterior segment infections. Aerozol-os (0.5 percent) is a nonirritating detergent.

Iontophoresis, combined with oral and topical application of the sulfonamides will produce maximum concentration in the cornea, aqueous, and anterior uvea in treating extensive corneal ulcer, endophthalmitis, and panophthalmitis.

Mecholyl, neostigmine bromide (prostigmine), and carcholin (originally marketed as doryl) have added greatly to the medical treatment of glaucoma. Mecholyl

chloride, 10 percent, with prostigmine, 3 percent, is an excellent miotic for patients with chronic simple glaucoma that cannot be controlled with pilocarpine and eserine. For acute congestive glaucoma, inject morphine sulphate (0.25 gr.) and instill mecholyl, 20 percent, and prostigmine, 5 percent (1 drop every 10 minutes for 7 doses). If intraocular pressure is not reduced after 1½ hours, give a retrobulbar injection (25 mg. of mecholyl in 1 c.c. procaine, 2 percent). The antidote, if necessary, is atropine 1 to 2 mg. Continue mecholyl and prostigmine drops for five additional doses. These drops are also recommended as a collyrium every 10 minutes for 1 to 2 hours, preoperatively, to reduce intraocular pressure.

Carcholin is valuable as a "rest therapy," after which the patient may be more responsive to the use of the usual miotics. In a 0.75 percent concentration, it is less irritating than pilocarpine and eserine and does not produce allergic dermatitis or conjunctivitis. Carcholin drops are not surface active. Vigorous massage for two minutes after instillation is necessary to increase absorption and the drug's effectiveness.

Dr. Smith stated that the extravagant claims made for vitamins in ophthalmic therapy have not been substantiated. He prescribes vitamin A for old, feeble patients with recurrent catarrhal ulcers, keratoconjunctivitis sicca, and mild forms of epithelial dystrophy. Vitamin B and B complex are effective in toxic amblyopia and retrobulbar neuritis. Vitamin B₂ is effective in rosacea keratitis. Vitamin D, in combination with vitamin A, is helpful for phlyctenulosis and severe blepharitis in children. Dr. Smith questioned the efficacy of vitamin C. The indications for vitamins K and P are limited. Considerable progress has been made in decreasing the irritation of eye drops and

improving their effectiveness by the use of solutions isotonic with tears, by standardization of the pH, and by the use of buffer solutions.

The detergents or "wetting agents" have been shown to accelerate the absorption of drugs like carcholin and the sulfonamides, but unfortunately these agents have an irritating and deleterious effect on corneal epithelium. Detergents should not be used in eyes with corneal abrasions.

Dr. Smith referred briefly to dibutoline sulfate, the newly described surface-active mydriatic and cycloplegic, which can be used safely in patients sensitive to the atropine drugs.

Leon H. Ehrlich,
Secretary.

COLORADO OPHTHALMOLOGICAL SOCIETY

November 17, 1945

DR. WALTER OHMART, *president*

DRUSEN OF THE OPTIC DISC

DR. WILLIAM M. BANE reported on Mrs. R. H. C., a 38-year-old white woman with general good health. She noticed, six years ago, that the pupil of the right eye was dilated. No cause was found. She was seen by Dr. Riche at that time. Neurologic findings were negative. There was no history of injury. Glasses were ordered 5 years ago, by an optician. Examination: R.E., 5/20; L.E., 5/20. The media were normal. Refraction was performed and glasses were ordered for myopia giving vision of 5/4 in each eye. Each disc was partially covered with excrescences which are called drusen.

According to Duke-Elder, drusen are really hyaline bodies made up of concentric laminations with no cellular structure nor capsule. They are supposed to be de-

rived, as is Bruch's membrane, from pigimentary epithelium displaced into the disc. Fuchs says they are of neural origin.

The appearance varies from flat masses to grapelike elevated clusters. They are located at the edge, center, or completely covering the disc. The condition is usually bilateral and may be associated with similar formations in the macula or elsewhere. It occurs in all ages but is most common in the aged and in the presence of retinal disease. If pressure on nerve fibers occur, there may be some atrophy and field changes.

ANIRIDIA OR IRIDEREMIA

DR. WILLIAM M. BANE reported on the case of a white boy, aged five years. This boy was seen several months ago at the clinic. Both eyes were similar, exhibiting the typical picture of aniridia, a rare congenital defect in which the iris is not completely absent but only a short rudimentary stump can be observed, hidden behind the cornea-scleral margin. The pupil occupies the whole area of the cornea, and the margin of the lens, the zonular fibers, and the summit of the ciliary processes may be observed. In this case, the lens margins were flattened at the six-o'clock position, indicating, here, a contraction of the capsule where the zonular fibers had probably ruptured. The boy exhibited no evidence of poor vision, and had no nystagmus nor photophobia, which so often accompanies this condition. The anterior chambers were normal in depth, and the lenses were neither ectopic nor cataractous. The history of heredity in this case was negative.

Discussion. Dr. Fritz Nelson and Dr. John Long suggested the tattooing of an iris on the cornea. Dr. W. T. Brinton mentioned a case of traumatic aniridia in which the eye was not sensitive to light. Dr. Morris Kaplan suggested colored contact lenses.

MEDULLATED NERVE FIBERS

DR. WILLIAM M. BANE reported on Mr. C. M. S., age 42 years. His condition, of opaque nerve fibers of marked degree which almost surrounded the disc of the left eye, was shown to illustrate the fact that elevation sometimes is noted. In this case, it measured about 2D. and could be distinctly observed by parallax. Medullated nerve fibers are not observed in the newborn, but develop after birth, and, therefore, are not considered congenital.

MALIGNANT MELANOMA

DR. R. W. DANIELSON presented a report of two cases.

Case 1. J. T. S., a 32-year-old man, who had been seen first in November, 1942, because of cloudiness of vision of the left eye, of two-weeks' duration. Vision was: L.E., 20/20; R.E., 20/15. No lesion of the media or fundus could be found, and the peripheral field was normal although there was a questionable enlargement of the blind spot. He was treated with typhoid vaccine, but by July, 1943, vision was 20/25.

In August, 1944, a faint, dark, choroidal elevation above the left macula was first noted. Vision was 20/25, but no central-field defect could be found corresponding to the lesion. However, by June, 1945, there was a small scotoma near fixation which had enlarged considerably by October, 1945.

At the time of presentation, vision was 20/40. The elevation had increased 1D. in five months. Tension was 20 mm. Hg (Gradle-Schiøtz). There were a few punctated hemorrhages in the retina, especially over the elevation. General examination had revealed no abnormality elsewhere. No foci of infection were found, and the Kahn test was negative. No melanin was present in the urine. The patient was presented for opinions as to the advisability of enucleation.

Dr. Danielson said that no transillumination had as yet been tried because of the scotoma's location but that even if some shadow did show, it would not prove a melanoma. In fact, as was pointed out, there is, as yet, no positive test or manner of examination by which a differential diagnosis between an early melanoma and other lesions of the choroid can be made. It was mentioned that it seemed somewhat ironic to have means of analyzing the composition of stars millions of miles away by spectroscopy, but no way of telling the composition of a structure close at hand. It was thought that someday there might be a device, like radar perhaps, whereby reflected rays might give an inkling as to the content of a tumor. In the absence of such an imaginary device, it was hoped that X ray might be sufficiently refined so that it would help in diagnosis and that the path to progress would lead to the finding of some chemical which, when injected intravenously, would have a selective affinity for melanin and would be radiopaque. If such a chemical could be found, it would also be of value in searching for possible metastases. Perhaps melanin so treated might be mixed in vitro, be injected and be found to have selective affinity for a melanotic tumor which ordinarily produces melanin.

Case 2. Dr. R. W. Danielson also presented R. M. A., a 69-year-old man, who had noticed a progressive loss of vision in his right eye for about a year. He had had no pain or inflammation in the eye. On examination, a large, brownish-black, pigmented mass was found hanging from the ciliary body and anterior choroid superiorly. Tension was 11 mm. Hg (Gradle-Schiotz). The peripheral field showed generalized contraction rather than an inferior defect, as one would expect. The fundus was normal except in the region of the elevation. The affected

area transilluminated very poorly. An interesting feature was the presence of an opacity of the lens capsule near the tumor, similar to the case shown by Dr. Fritz Nelson at the last meeting.

After reviewing some recent literature, Dr. Danielson pointed out the high incidence of death, even when the eye had been removed quite early. He conjectured the possibility that these tumors tend to metastasize in their incipiency, rather than later when, perhaps, some reactive mechanism tends to bind the tumor cells in place. He wondered whether the opacity in the lens is due to pressure, to some toxic action, or to an involvement of the ciliary nerves supplying that part of the eyeball, since malignant melanomata are now thought to have their genesis in neural elements.

MARCUS GUNN SYNDROME

Dr. JOHN C. LONG presented the case of J. A. S., a five-year-old boy with a Marcus Gunn syndrome. The boy showed a marked ptosis of the left upper lid. The left lid opened widely when the jaw was opened; especially when the jaw was thrust to the right. Opening of the left lids was much less pronounced when the jaw was thrust to the left. On chewing, there was a rhythmic raising and lowering of the left upper lid. This condition was somewhat more pronounced when the eyes were turned downward. There was also a paralysis of the left superior rectus muscle. The defect had been present since birth.

HERPES ZOSTER

Dr. MUIR presented E. H., a white man, aged 76 years. In May, 1945, he had an eruption which, on the right, followed the distribution of the Vth nerve. This eruption was accompanied by pain. When he was seen in the clinic at Grand Junction, June 6, 1945, the eruption was near-

ly gone, but the pain persisted. The patient also complained of diplopia.

Three 5,000-unit dosages of diphtheria antitoxin were given. Four Kahn tests were: (1) positive, (2) positive, (3) doubtful, (4) negative. Spinal test was negative. He was also given alcohol and cocaine injections into the medial aspect of the right eyebrow, which only made the pain worse.

Seen at the Colorado General Hospital for the first time on October 21, 1945, he was referred to dermatology, where he was given six injections (2 c.c. each) of thiamin over a 12-day period. Since the patient still complained of pain, cobra venom treatments were started on November 15, 1945.

Examination at the eye clinic revealed: On November 2, 1945, asymptomatic. Vision was R.E., 20/100; L.E., 20/30, plus. The patient said that ptosis was disappearing, and that there had been no diplopia for a long time. Pain returned on November 13th. The cornea of the right eye showed diffuse, generalized, superficial, punctate staining areas. On November 15th, only the inferior portion now stained. At present the residuals of herpes zoster ophthalmicus are present on the right forehead and eyelid, especially on the palpebral conjunctiva. Both the ptosis and diplopia were transient. Corneal staining recurred after an interval in which the patient was free of ocular symptoms.

Discussion. Dr. Katherine Chapman suggested the injection of pituitary and the local application of collidum. Dr. J. Shields advised the use of penicillin, locally, and Dr. J. Long suggested the use of convalescence serum.

Gertrude Hausmann,
Secretary.

CHICAGO OPHTHALMOLOGICAL SOCIETY

November 19, 1945

PETER C. KRONFELD, *president*

CLINICAL PROGRAM

(Presented by the Department of Ophthalmology, University of Illinois Medical School)

SPASTIC DIPLEGIA WITH HOMONYMOUS HEMIANOPIA

DR. EDWARD J. HORICK said that C. R., a woman, aged 33 years, complained that her eyes tired quickly with near vision. Refraction showed a -3.00 sphere in each eye and a divergence excess, 26 degrees for near. Exercises helped considerably, and she is now comfortable with near work.

Visual field study showed a homonymous hemianopia with sparing of the fixation area. She had been unaware of the defect. The neurologic report was antenatal disease of the brain. The condition may be regarded as a variation of Little's disease.

GROUPED PIGMENTATION OF THE RETINA

DR. STEPHEN W. SUKUMLYN presented M. L., a white boy, aged 17 years, who was referred from the Department of

Pediatrics and Endocrinology where he was studied for obesity. Laboratory tests were negative. External examination of the eyes was negative. Visual acuity was:

R.E., 1.5-2; L.E., 1.5-3. He had never worn glasses.

Examination of the fundi after homatropine refraction revealed normal papillae and normal retinal vessels. The immediate area surrounding the discs and extending to the temporal side to include the macular region was of normal orange color. In the right eye, toward the nasal side, there were numerous various-sized dots, spheres, ovals, and other irregularly shaped, sharply defined spots of pigmentation gradually increasing in number as they receded from the disc toward the equator. The pattern had a tendency to run in groups, the groups forming a congestion which followed the equator of the eye, becoming more scant on the temporal side. The picture in the left eye was similar, although less striking. The pigment ranged in intensity from light to dark gray, and its position in the retina was below the retinal vessels and above those of the choroid.

Peripheral fields were normal for red, white, and blue; central fields showed no scotomata.

This is a typical case of group pigmentation of the retina. It has normal visual acuity, normal central and peripheral fields, and an abundance of pigmentary plaques in the retina. Comparatively few cases have been recorded in the literature, under various names such as: melanosis of the retina, group pigmentation of the retina; nevoid pigmentation of the fundus, and congenital melanosis of the retina. The explanation of the position of the pigment as given by Ida Mann is "an atypical differentiation of isolated cells of the inner wall of the cup, each of which has developed pigment and then divided to form the small clump of cells seen in the pigmented spot." Parsons, after microscopic examination of such an eye in 1904, explains the plaques as aggregations of deeply pigmented cells of

retinal epithelium which found their way into the layers of the retina through spaces where rods and cones had failed to develop.

BILATERAL EXTERNAL RECTUS PARALYSIS (CONGENITAL)

DR. ROOSEVELT BROOKS said that D. V., aged 17 months, was first seen in September, 1944. The mother stated that the child's eyes had always turned in. There was no history of birth injury.

On examination, both eyes turned toward the nose 40 to 45 degrees with little or no rotation externally. The child turned her head to see at the extreme right or left. When looking to one side, there was increased effort to converge with one eye but no noticeable external rotation of the opposite eye. The pupils reacted to light, and the discs appeared normal. No visual findings could be obtained. Attempted refraction under atropine cycloplegia gave: R.E., with a +2.50 D. sph. \ominus + 1.25D. cyl. ax. 15°. No figures were obtainable for the left eye because of poor fixation.

At the most recent examination, there was definite fixation with the right eye but no external rotation beyond the midline. The left eye still did not rotate externally, and the child cannot fix with this eye. In other words, there has been some improvement in external rotation of the right eye during the year that she has been under observation.

According to Whitnall, congenital factors are largely due to errors in development by cleavage from the common pre-muscular mesoblastic mass. Harold Gifford reported a series of cases in 1926, including unilateral and bilateral paralysis of external recti. He stated that the defect seemed to be due to hypoplasia or simple lack of development of the nucleus as opposed to the theory of intra-uterine disease. Some of his cases were associated

with other congenital defects, such as reduced adduction, paralysis of the facial nerve or tongue, or defects of the hands. However, no other congenital defects were observed in this case. The closeness of the 6th and 7th nuclei rather speaks for a central lesion. Birth injury is undoubtedly responsible for many supposed congenital ocular-muscle paralyses. The greater frequency of paresis of the left external rectus would lead to the belief that even moderate pressure in the birth canal will explain many cases.

HEREDO-FAMILIAL MACULAR DEGENERATION

DR. MARTHA RUBIN FOLK presented four cases.

Case 1. T. R., a white man, aged 25 years, complained of failing vision which began at the age of 18. Two sisters suffer from the same condition; the vision of the parents is apparently normal.

External examination of the eyes was negative. Vision was: R.E., 0.2; L.E., 0.2. The pupils reacted to light and accommodation. Examination of the fundi showed, in the macular region, a triangular area about one-third disc diameter, with some pigmentary disturbance as a pepper and salt macula. In the center of the macula, a darker pigmented patch was seen. The central fields showed a central scotoma, and the peripheral fields showed a 30-degree contraction for red. Treatment included lextron ferrous capsules and vitamin B₁.

Case 2. B. G., a white woman, aged 42 years, was first seen in September, 1945, with a complaint of gradual loss of vision which began at the age of 14 and was progressively getting worse. She married at the age of 21 and had three children, one of whom had trouble with her eyes. There were mild pigmentary changes in the macula with no loss of vision. The pa-

tient has one brother and one sister with similar eye conditions.

On examination, the eyes were negative externally. Vision was: R.E., 16/200; L.E., 0.4. Ocular movements were normal; irides were blue; pupils reacted to light and accommodation.

In the right macula, an atropic lesion with sharp margins was seen. This lesion, about two disc diameters in size, was sprinkled with pigment and gave a salt and pepper appearance. The left macula had a similiar lesion. The red fields were contracted to 30 degrees and also showed a central scotoma. Physical and laboratory examinations were negative. Treatment included vitamin B₁ (5 mgm.).

Case 3. S. K., a white woman, aged 34 years, gave a history of difficulty in reading as far back as she could remember. One sister and one brother had similar eye conditions. The mother and father were unaffected.

Vision was R.E., 0.1; L.E., 0.1. Ocular movements were normal. Pupils were 4 mm. in diameter and reacted to light and accommodation. In the macula was seen an apple-shaped atrophic area with sharply demarcated edges, and with a blood vessel running through the central portion of the lesion giving a salt and pepper appearance. A black-pigmented patch on a yellow base was seen in the center of the lesion. There was slight pallor of the disc. A similar lesion was seen in the left eye. Fields were normal. Physical examination and Wassermann test were negative. Red blood count was 3,500,000. Treatment included lextron ferrous capsules and vitamin B₁.

Case 4. This 26-year-old Negress was first seen on November 9, 1945, complaining of cloudy vision and pain in both eyes of two-weeks' duration. The first symptoms appeared when she was 17, at which time she was unable to see the blackboard

in school. At the age of 21, she was fitted with contact lenses.

There was a slight narrowing of the right palpebral fissure and mixed injection of the right bulbar conjunctiva. Both corneas were conical. An ectactic-leukomatous opacity about 4 mm. in size covered the papillary area, becoming more nebulous as it reached the limbus. Fine macular opacities were present, centrally and laterally, in the left cornea. The left fundus was seen merely as a red reflex. The right cornea stained with fluorescein; the left corneal epithelium was intact. The right anterior chamber was deep and, due to opacities, the fundus could not be made out. Refraction revealed a compound myopic astigmatism. Vision was: R.E. with a $-4.00D.$ sph $\ominus -3.00D.$ cyl. ax. 165° = ability to see fingers; L.E. with a $-3.50D.$ sph. $\ominus -3.25D.$ cyl. ax. = 0.1.

Diagnosis was: (1) bilateral conical cornea; (2) ectasia of the right cornea; (3) acute keratitis. Treatment consisted of pilocarpine solution, bichloride Hg ointment, and a tight bandage. This caused a recession of the cone to about 3 mm.; the mixed injection subsided; and the cornea improved.

In spite of the fact that the patient had worn contact glasses continuously eight hours a day for two years, the ectactic condition of the cornea was not alleviated and the degenerative processes continued.

RETINITIS PIGMENTOSA

DR. HAROLD D. BOCKOVEN presented two patients from Dr. Apple's service.

Case 1. A white man, aged 32 years, was first seen in August, 1945, complaining of marked loss of vision beginning at the age of 10. After examination at that time, he entered a school for the blind. Vision decreased progressively and, at the age of 21, he could no longer read. He has al-

ways been able to go about alone, having used a white cane for 10 years.

Family history showed that his father and mother were cousins. There were five children. An older brother was in a mental institution at the age of 13; the patient believed his brother's eyes were normal. Another older brother developed poor vision at the age of 10 and was totally blind at about 28 years of age. A younger brother had weak eyes and could no longer read at the age of 21. The sister's eyes were normal.

On examination, visual acuity, bilaterally, was light perception. Retinoscopy revealed refraction corrected by a $+3.00D.$ sph. $\ominus +1.00D.$ cyl. ax. 90° , bilaterally. There were moderate vertical nystagmoid movements, more marked at the extremes of rotation. Pupils were 5 mm. in diameter and reacted poorly to light. There were discrete, sharply outlined, minute opacities situated in the anterior third of each lens, more marked on the left. These opacities were bluish when observed with the slitlamp.

The discs were pale and waxy in appearance, with indistinct edges. Both arteries and veins were moderately constricted. The fundi were tessellated, and there was a moderate amount of pigment of the bone-corpusele type situated equatorially, frequently in close proximity to the retinal vessels. There was marked pigmentary disturbance at the left macula; both maculas appeared moth-eaten. Minute aneurysmal dilatations were present along the left superior temporal artery.

Case 2. A 50-year-old white man who was first seen October 17, 1945, complained of progressive loss of vision for five years, particularly in dim light. There was no history of past inflammation.

The patient had four brothers, two of whom had eye trouble; three sisters were normal. One brother, aged 46 years, had

had defective vision for 12 years, characterized early by night blindness, and was now practically blind. A second brother had a marked visual handicap, the nature of which is not known. There was no other significant family history, such as intermarriage.

Visual acuity equaled 0.1, bilaterally, and could not be corrected. Externally, a bilateral, diffuse, conjunctival injection and arcus senilis were noted. The pupils reacted to light and accommodation. The crystalline lenses were hazy bilaterally, posterior polar opacities being present. On fundus examination, the discs were pale and appeared waxy. The retinal vessels, particularly the arteries, were greatly attenuated. Both fundi were tessellated. Pigmentary deposits of a cobweb appearance were present equatorially. Bone-corporuscle type pigmentary deposits were present in both fundi, above and nasally. Some of these covered the blood vessels. Several large accumulations of pigment were situated peripherally. Bilaterally there was a peripheral form field, limited to from the 8- to the 10-o'clock positions, and a red field of 5 degrees.

PERSISTENT TUNICA VASCULOSA LENTIS WITH FIBROUS HYPERPLASIA

DR. E. M. GREEN presented three cases from Dr. Apple's service.

Case 1. D. G., aged 29 months, was first seen at the age of five months and was one of twins born eight weeks prematurely. His weight at birth was 3 lbs., 12 oz. Two preceding pregnancies resulted in normal, full-term deliveries. The three siblings, including the twin, had had no ocular complaints and follow-up revealed no pathologic condition in the twin. There was no history of acute illness in the puerperium or in the patient postnatally.

Physical examination revealed no gross pathologic condition, excepting the ocular defects. Bilateral microphthalmos and a

searching horizontal nystagmus were noted. Photophobia to strong light was present. An apparent dense, white corneal opacity occluded the iris on the right, temporally. The anterior chambers were shallow and the irides were light blue, with indistinct markings. With mydriatics, the right pupil dilated from 2 to 3 mm., irregularly and the left to 7 mm., evenly. On the Purkinje test, the light reflex from the posterior capsule of the lens was absent and, behind both lenses, was seen an opaque, white membrane on which blood-vessel remnants could be identified. A faint-red reflex was obtained from the nasal half of the left pupil. Tactile tension was normal.

The patient has been seen at regular intervals, and there has been no definite change in the eye findings.

Case 2. A. B., aged 11 months, was first seen at the age of five months with a history of increasing prominence of the right eye for the preceding two months. The patient was born 10 weeks prematurely and weighed 2 lbs. 13 oz. at birth. Otherwise, the history was of no significance.

Physical examination was negative except for the eyes. The left eye was microphthalmic. The right eye was enlarged, measuring 14 mm. in diameter. The left eye measured 10 mm. in diameter. The irides were light blue with indistinct markings, and the anterior chamber was absent or negligible, on the right, and shallow, on the left. The right eye was very firm on tactile tension, considerably more so than the left. Variable tonometric readings confirmed the tactile impression. An opaque, white membrane was noted behind the temporal portion of the right lens but, through the nasal portion, a clear view of a normal fundus and non-cupped disc was obtained. In the left eye, the membrane was more extensive, and only a faint-red reflex was obtained through the nasal half. Ciliary processes

extending in the left pupil were seen.

After a trephine of the right eye was performed on June 14, 1945, no further enlargement occurred. Normal ocular tension was obtained.

Case 3. P. P., aged two years, was first seen in October, 1945. She was born 10 weeks prematurely and weighed 1 lb. 13 oz. There was no history of acute illness during the puerperium or in the patient postnatally.

Physical examination was negative except for the eye findings and prominent frontal bosses. Photophobia to strong light was present. Both eyes were small and deep set, and a searching horizontal nystagmus was present. An apparent, whitish corneal opacity obscured the superior portion of the irides, bilaterally. The anterior chambers were extremely shallow or absent. The irides were light blue, the markings indistinct, and they had a fetal appearance. The pupils dilated irregularly, the right from 3 to 4 mm. and the left from 2 to 3 mm. with homatropine. The lens substance was clear, but the light reflex from the posterior lens

capsule was absent. Behind both lenses was seen a thick, white, opaque membrane. There was no red reflex on either side. Laboratory and x-ray studies were not significant.

On October 10, 1945, a combined linear extraction of the right lens was performed, and an attempt was made to push the membrane to one side. Postoperatively, no iris coloboma was noted, and the small pupil present was occluded by fibrous adhesions. A wide complete iridectomy was performed on November 10, 1945. Nine days later, the findings showed the white membrane presenting anteriorly through a large pupillary opening.

SCIENTIFIC PROGRAM

LEGAL OPHTHALMOLOGY

Mr. Joseph Hinshaw read a paper on this subject which has been published in this Journal (September, 1946). Discussion was by Drs. Guibor, Soper, Hoffman, Mundt and Zeiss, and in closing by Mr. Hinshaw.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois; Society Proceedings to Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to Dr. F. Herbert Haessler, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Alhnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE 1946 ACADEMY MEETING

The week of October 13th to 18th, the Palmer House in Chicago unveiled one of the biggest and best conventions of the American Academy of Ophthalmology and Otolaryngology in its 51 years of existence. More than 3,000 members and guests registered, and every facility was bursting with more or less happy doctors in search of knowledge. The Academy meeting has often been likened to a three-

ring circus, and the similarity continued in force this year, perhaps with a few more rings added.

The presence of many ex-medical officer members, old and new, resulted in impromptu reunions of veterans from the various theaters of operations, and many a hospital campaign was refought and experiences reviewed.

There were several innovations arranged for by the officers after much

thought and hard work. On the whole, these innovations were happy ones. The alternation of the Eye and Ear, Nose and Throat divisions in scientific assembly and instruction hours resulted in less crowding and more efficient handling, especially in the courses. The scientific programs were better than usual. The interspersing of motion pictures between scientific papers was an interesting experiment, meeting with favor by some and disfavor by others. In spite of some criticisms heard here and there, it would seem that most of the members enjoyed the new arrangement. The hall was crowded even through the last session.

The instruction courses were packed, and most of them were completely sold out. After the drought of the war years, everyone seemed thirsty for information and eagerly drank at the springs of knowledge set up in prosaic hotel rooms by the efficient secretaries.

The Jackson Memorial Lecture was given on the evening of October 16th by Dr. Alan C. Woods, the president-elect. The title of his comprehensive and stimulating address was "The influence of hypersensitivity on endogenous uveal disease." It is a valuable contribution to ophthalmology, summarizing what has been the author's life work of deep thought, study, and experimental research.

The Ear, Nose, and Throat members enjoyed an extra fillip in acting as hosts to the Pan-American Congress of Otorhino-laryngology and Broncho-esophagology which immediately followed the convention. The presence of outstanding South American scientists and particularly their vivacious and charming wives made the meeting a colorful one and added much to the gaiety of the gathering.

The scientific exhibits were well-chosen and displayed. This important feature of the Academy was always filled with members seeking what was new, and none left

without adding something of great value to himself and to his patients. Ten of the 24 displays were from the ophthalmic division. Awards were given to Dr. Donald J. Lyle of Cincinnati, Ohio, for the teaching value of his extensive exhibit on "Neuro-ophthalmology;" to Dr. Walter H. Fink of Minneapolis, Minnesota, for the originality of his exhibit on "An anatomical study of the oblique muscles of the eye;" and to Dr. A. D. Ruedemann of Cleveland, Ohio, for the excellence of presentation of his exhibit on "Plastic eye implant." This last won the gold medal at the A.M.A. convention in San Francisco in June.

It was good to see so many familiar and friendly exhibitors displaying their goods and receiving orders in the Technical Exhibit Hall. Many of the orders will take a long time to be filled in these days of reconversion shortages, of course. But the display was there, with great promise of good things to come, and it was like old times. The war years had receded, and one was back again, seeing, handling, comparing, and discussing the tools of his trade with his colleague and exhibitor just as if a cataclysm had not occurred.

At the luncheon given to the faculty by the president, Gordon B. New, the Leslie Dana Medal of the National Society for the Prevention of Blindness, the St. Louis Society for the Prevention of Blindness, and the Association for Research in Ophthalmology was presented to Harry S. Gradle for his outstanding contributions to the prevention of blindness, to ophthalmology, and to the teaching of ophthalmology. Conrad Berens gave the presentation citation which will be printed in the Journal in a subsequent issue, and the medal to Mrs. Gradle representing her husband who was prevented by illness from being present, much to our regret and sorrow, for Harry Gradle is one of our best loved members.

In spite of its size, which is increasing yearly, the Academy functions on well-oiled and well-guided ball bearings. One need have no misgivings as to its future, for it is here to stay in very much its present form for many years to come, because it gives utmost service to each of its eager and loyal members.

Derrick Vail.

TRAINING NONMEDICAL HELPERS IN OPHTHALMOLOGY

As to possibilities of development for the good of ophthalmology, and therefore of the general public, perhaps the most important paper presented to the recent San Francisco meeting of the American Ophthalmological Society was that read by Parker Heath on "Medical Assistance at Professional Level."

Heath recognizes a serious shortage of physicians, not only as existing at the present time, but as likely to continue for some years to come. The war has had much to do with causing this shortage which is especially serious in the field of ophthalmology; but some of us may be disposed to question whether the shortage is more particularly one of personnel or rather of effective training of that personnel.

The remedies so far proposed include "larger classes at undergraduate level, increasing the number of residents and internes, provision for more fellowships, refresher courses, and basic training programs in the specialties."

The medical profession, we are reminded, has trained special groups of lay persons to aid in caring for the sick. These groups include nurses, laboratory helpers, X-ray technicians, office employees, and special workers in research. The only department in which ophthalmology has made a serious attempt to cope with the problem of training expert assistants is that of orthoptics.

Heath suggests that ophthalmology is probably more adaptable to professional assistance than any other specialty. Aspects of ophthalmology suggested as lending themselves to special training and utilization of lay assistants include refraction, muscle balance, tonometry, external and ophthalmoscopic examination, photography, some forms of therapy, perimetry, screening tests in schools and industry, the care and preparation of instruments, assistance during operations, laboratory procedures, the fitting of contact glasses, and the assembling of material for scientific essays.

It is apparently contemplated that non-medical persons, expertly trained for these multifarious activities, shall assume much of the work at present undertaken by medical graduates who either have received a more or less complete training in ophthalmology or are seeking such training under the preceptorship of the medical chief with whom they are associated.

It is pointed out that at the present time many of us delegate parts of our examination of patients to personnel trained by the preceptor method, "a method which requires many years and does not turn out enough well-rounded trained people to meet the demands or the possibilities." To increase the numbers of such persons, and to insure their proper training, Heath would establish a special college curriculum of four years and leading to a bachelor's degree. The first two years of such a course would be taught by the usual literary and scientific faculties, while the last two years would be devoted to the medical field, and responsibility for them would devolve upon medical teachers. The author's outline of a curriculum for these last two years includes most of the subjects ordinarily taught to graduate students in ophthalmology. For example, it is proposed to devote 240 hours to anatomy including

dissection, 576 hours to refraction, 216 hours to physiologic chemistry, 144 hours to histology of the eye, 216 hours to pathology, 144 hours to clinical and laboratory technique, 72 hours to ocular muscles, 280 hours to orthoptics, and 200 hours to perimetry.

It may be assumed that this proposal to create an important new professional group has grown out of the urgent need of those who are carrying on large ophthalmic practices, as well as in many instances administering important public clinics. Such leaders in ophthalmology have no doubt tried and found wanting the usual employment of medical assistants or associates, as well as the rather slow and laborious process of preceptorship as applied to a well-educated secretary or nurse. Many medical assistants and associates have been grievously missed during the war period. Some of them have returned from war service anxious to carve independent careers.

To many of us, sympathetic consideration of the present proposal may suggest questions as to its effect in the first place upon the individual ophthalmologist who might employ the new type of graduate, and in the second place upon the practice of ophthalmology as a whole.

How long, we may inquire, would it take not merely to induce a number of important colleges to create such a course leading to a degree, but also to interest a large body of students in such a course? At first the applicants are likely to be drawn from the ranks of those high school students or graduates who have already felt themselves impelled toward the regular nurse's training. Further, how long would it take to induce a large number of ophthalmologists to replace their present helpers by such new graduates?

Allowing for the time necessary to attract a body of students, for the length of time to be occupied by the course itself,

and for the education of the profession of ophthalmology in the utilization of such graduates, it seems not unlikely that ten or twelve years would be a moderate estimate of the period within which we could expect a large number of such non-medical graduates to have been launched upon their new career.

To what extent would the provision of such highly trained nonmedical office assistants tend to reduce the opportunities for development of young ophthalmologists who might expect to start their careers as assistants to established practitioners of the specialty? Is the desire to establish such a nonmedical graduate group partly based upon the fact that medically qualified assistants have ambition beyond that which may be expected of a lay assistant, and are apt sooner or later to undertake their own competitive practice of ophthalmology?

Is it to the advantage of the general public that much of the practice of ophthalmology shall be concentrated in the hands of a few leaders who make use of lay assistants, or will such public advantage be best served by the training of as many medical ophthalmologists as the market can support?

Is there not much to be said in favor of the individual and direct personal relation between ophthalmologist and patient rather than the delegation of professional tasks to a lay assistant who reports back to the ophthalmologist?

Would not the length of time necessary to produce substantially useful results from the new proposal be better utilized in working toward the creation of improved facilities for the post-graduate training of medical men in ophthalmology?

Many leading ophthalmologists are at present excessively overburdened with the teaching of undergraduate and postgraduate medical students. Really intensive

training of those preparing for expert assistantship to ophthalmologists might be expected to add materially to the educational labors of those called upon to establish such facilities. If the training bestowed upon this new group of students is not of the highest possible quality, it is not worth giving at all.

Too many physicians practicing eye, ear, nose, and throat in the larger country towns are appreciably better trained in otolaryngology than in ophthalmology. Such men might easily delegate a large part of their work in ophthalmology, and especially in refraction, to a graduate lay assistant, who then might easily prove to be the rather effective competitor of an independent ophthalmologist in the same town. Such a contingency could hardly be regarded as generally advantageous to ophthalmology as a whole.

Is there any possibility that a considerable number of these specially trained lay assistants would be enticed into selling their services to osteopaths or chiropractors, or even to optical concerns which advertise expert examination in refraction?

Have not the older ophthalmologists, firmly established in their specialty, a moral duty to assist in the development of a younger generation of medical ophthalmologists rather than in the creation of a new nonmedical group of workers in the specialty and particularly in the practice of refraction?

In its ultimate elaboration, the proposed scheme for training of expert office assistants below the graduate medical level might prove of great public benefit, especially in the event of development of a large measure of socialization of medicine. Whether it would be of general advantage to the profession of ophthalmology, as at present constituted, is a question to which we may properly devote serious and deliberate consideration, bear-

ing in mind every conceivable aspect of the subject.

W. H. Crisp.

DI-ISOPROPYL FLUOROPHOSPHATE IN GLAUCOMA

During the past few years several new drugs have been introduced for the treatment of glaucoma. The most recent of these is Di-isopropyl Fluorophosphate (D.F.P.). The fluorophosphates have been shown to be powerful parasympathamimetic drugs due to their ability to destroy cholinesterase. They are quite toxic and during the recent war were considered as potential chemical warfare agents by both the enemy and ourselves. In the course of chemical warfare experiments, the marked miotic effect of D.F.P. on the pupil suggested its possible use in the treatment of glaucoma.

D.F.P. $[(C_3H_7O_2)_2 P O F]$ is a rather unstable compound with a faint fruity odor. Its freezing point is $-50^\circ C.$, and its boiling point is $183^\circ C.$ Its stability is greatly enhanced in solutions of peanut oil.

The recently published clinical investigations of McDonald and of Leopold and Comroe indicate that we have in D.F.P. a valuable addition to the arsenal of anti-glaucomatous agents. In many cases, it will control the intraocular pressure when the more conventional treatment with eserine and pilocarpine has failed. In others, it will be no more effective than these standard drugs have been. Its chief advantage seems to be in its prolonged action, and the lack of necessity for frequent instillations. Another valuable asset is its ability to overcome the mydriatic and cycloplegic effect of atropine. This will be welcome news to those ophthalmologists who have had the misfortune to deal with a case of glaucoma precipitated by cycloplegic examination, or by

the mistaken use of atropine for a miotic.

Like any other miotic D.F.P. may produce certain untoward affects. It can cause ocular and brow pain due to powerful ciliary spasm. Headache and photophobia have been complained of following its use. Systemic affects from absorption from the conjunctival sac have occurred in experimental animals; one drop of the full-strength solution in the eye of a rabbit has caused death within two to three minutes. Therefore, it is a drug to be treated with respect and not used indiscriminately. However, Leopold and Comroe have not found any systemic affects in man when employing it in 0.2-percent solution, an observation which agrees with this writer's experience.

Other series of cases must be studied before D.F.P. becomes available for general use. Time will tell whether or not it will prove as effective as preliminary reports make it appear to be.

Edwin B. Dunphy.

BOOK REVIEWS

OPHTHALMOLOGY IN THE WAR YEARS. Vol. 1 (1940-1943). Edited by Meyer Wiener, M.D. Clothbound, 1,166 pages, references, subject index, and author's index. Chicago, 304 South Dearborn Street, Year Book Publishers, Inc., 1946. Price, \$13.50 postpaid.

Thirty-six contributors, most of whom are widely known and all of whom are experts, combined under the able editorship of Dr. Wiener to produce a volume of great practical use and value to all English-reading ophthalmologists. The cruel war years, among other and less serious things, forced many ophthalmologists either through isolation in military service or through the overburden of

routine office work, to give up the reading of current ophthalmic literature, which is the life blood of progress in our great specialty. To fill in this gap in our knowledge, the present volume and its subsequent fellow were conceived.

The editor says in his preface that "it has been the purpose of the editorial staff to supply as complete a bibliography as possible and to give not merely an abstract but a running comment on articles which, in each editor's estimation, merited a review." These purposes have been amply fulfilled, to the great credit of the contributors and the staff. When one considers how busy these men and women were and are, what difficulties were encountered in obtaining the articles, the restricted lists of foreign journals and ophthalmic literature in general, and other hardships in war-time, one can but marvel that such a splendid and complete piece of work could result.

Each contributor read, digested, reviewed, and commented on anywhere from 50 to 800 published articles in his particular field. The expert judgment shown in discrimination makes each chapter an authority of the subject under discussion, and emphasizes the peaks of progress in our specialty in the years January, 1940, through December, 1943.

All parts of ophthalmology are covered, including, as well, comparative ophthalmology, hygiene, sociology, education and history, methods of examination, and industrial ophthalmology.

One is indeed proud of this achievement in American ophthalmology, and grateful for the wealth of ophthalmic literature, collected under such trying conditions, that is made available in one volume to all of us. That it will be fruitful and productive of ideas, useful in the solution of one's daily problems, and a ready source of reference and stimulation needs no comment. The editor, the contributors,

and the publishers are to be congratulated, commended, and thanked by ophthalmologists everywhere.

Derrick Vail.

DISEASES OF THE EYE. (Revised edition.) By Konstantin Pascheff. 495 pages, 288 illustrations, 12 plates. Sofia, University Publication, 1946.

This is the second edition of the first textbook on ophthalmology in the Bulgarian language, and it is supplemented by the ophthalmic advances made from 1929 to 1946. The author is a prolific contributor to ophthalmic literature, and he uses much of his published material in this book. The book is divided into 12 chapters, dealing with diseases of the orbit, lids, lacrimal apparatus, motor system, sensory and sympathetic systems, conjunctiva, cornea-sclera, uvea, visual apparatus, the lens and vitreous, and the

globe including glaucoma and anomalies of refraction. The last chapter deals with surgery as it is being performed in the author's clinic at the University of Sofia. Each chapter covers briefly methods of examination, congenital anomalies, circulatory disturbances, inflammation, degeneration, injury, tumor, prophylaxis, and therapy. The profuse illustrations with drawings, photographs, and microphotographs, and the condensed, although precise and clear, descriptive material will widen the ophthalmic horizon of the medical student without burdening him with much reading. The textbook is, nevertheless, sufficiently complete to be of value to the general practitioner and to serve as an excellent guide to the student of ophthalmology. Worthy of note are the plates of illustrations on trachoma and congenital ectopia of the lens.

Ray K. Daily.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

VISUAL TRACTS AND CENTERS

Damel, C. S., Dickmann, H. G., and Just Tiscornia, B. **Considerations on five cases of optochiasmic leptomeningitis.** *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Oct., p. 481.

The authors, who prefer the term optochiasmic leptomeningitis to the more common one of optochiasmic arachnoiditis, report their findings in five cases of this disease, in all of which the clinical diagnosis was verified at operation. The greater incidence of the condition in men in the second and third decades of life is stressed. The disease may be primary and the chiasm involved alone, or it may be secondary to other diseases affecting the central nervous system, such as encephalitis, tabes, and multiple sclerosis. The etiology is quite varied; trauma, focal infection, tuberculosis, and syphilis are the most common causes. While polymorphism of the visual fields is characteristic of the disease, concentric and irregular contraction is the most fre-

quent perimetric occurrence. The fundus generally shows optic atrophy, although this may exceptionally be accompanied by edema. The authors favor early surgical intervention, not only in cases of known etiology, in which the medical treatment fails to arrest the progress of the disease, but also in those cases in which the etiology is unknown. They believe that a judicious combination of medical and surgical treatment will improve the percentage of favorable results. (Visual fields, tables, and bibliography.)

Godtfredsen, Erik. **Ophthalmologic and neurologic symptoms of malignant nasopharyngeal tumors.** *Acta Ophth.*, 1944, Supplement 22, pp. 273. (See Section 15, Tumors.)

Hughes, E. B. C. **Some observations on the visual fields in hydrocephalus.** *J. Neurol. Neurosurg., and Psychiat.*, 1946, v. 9, Jan., pp. 30-39.

Little attention has been paid to chiasmal changes produced by a dis-

tended third ventricle in obstructive hydrocephalus. There has been some confusion because of papilledema and secondary optic atrophy. The patients studied in this series are without evidence of optic atrophy. The earliest change is very small paracentral scotomas in the apex of the lower temporal quadrant which is usually bilateral. The scotomas are thin, have small visual angles, and are usually centrocaecal. As the scotoma gradually enlarges the adjacent isopters become involved locally. The next change is a depression of visual acuity in the affected quadrant and is characterized by a recession of the central isopters and graying of the affected fields (white objects appear hazy, dirty, gray, pale green). Graying is seen more commonly in chiasmatal lesions, and stops at the midline inasmuch as crossed fibers are involved. With further progress the depression type of field comes into play and a gradual loss of central isopters ensues until most of the lower temporal quadrant is lost. Later some graying occurs in the nasal field. Small scotomas may also appear in the upper temporal quadrant.

I. E. Gaynon.

Porsaa, Kaj. The central visual field after occipital lobectomy. *Acta Ophth.*, 1944, v. 22, pt. 2, pp. 243-260.

Porsaa reviews the literature on bilateral representation of the macula, and reports five cases of hemianopsia without sparing of macular vision after occipital lobectomy for neoplasm. In one case, there was macular sparing preoperatively, but it was lost after the operation. Porsaa believes that these observations conclusively prove the absence of bilateral cortical macular representation. The sparing of the macula, when it is found, is to be attributed to an extensive macular repre-

sentation in the calcarine area, part of which is left intact. Ray K. Daily.

Traquair, H. M. The nerve fibre bundle defect. *Trans. Ophth. Soc. United Kingdom*, 1944, v. 64, p. 3. (See Section 10, retina and vitreous.)

Zeligs, M. A. and Joseph, G. F. Unilateral internal ophthalmoplegia. *Arch. Neurol. and Psychiat.*, 1945, v. 54, Nov.-Dec., p. 389.

Isolated unilateral ophthalmoplegia may be the only clinical sign in a patient with syphilitic meningitis. A case history illustrating such an occurrence is presented. The diagnostic importance of serologic study in cases of unexplained pupillary paralysis is emphasized. The rapid therapeutic response to penicillin therapy is mentioned. The probable anatomic site of such a lesion is postulated. Theodore M. Shapira

EYEBALL AND ORBIT

Bardram, M. T. Progressive exophthalmos (so called malignant exophthalmos). *Acta Ophth.*, 1944, v. 22, pt. 1, pp. 1-26.

The literature of exophthalmic ophthalmoplegia is reviewed, and three cases following thyroidectomy are reported. All three cases had an increased output of gonadotropic hormone, and one had an increased metabolic rate with other symptoms of thyrotoxicosis. In one patient the exophthalmos abated after a Naffziger decompression; in the other two it was controlled by conservative treatment. (3 illustrations.)

Ray K. Daily.

Bengisu, N. A crouzon type of craniofacial dystosis in a father and daughter. *Oto-Nöro-Oft.*, 1946, v. 1, pp. 1-5.

The author reports two cases of cranio-facial dystosis characterized by the triad of exophthalmus, and deformity of the cranio-facial and maxillary bones. The anterior segment of the father's eyeball had been amputated because of lagophthalmic keratitis. The daughter had an early postedematous optic atrophy. I. E. Gaynon.

Bertotto, E. V. **Congenital paralysis of the lateral rectus and melanosis bulbi.** *Anales Argentinos de Oft.*, 1945, v. 6, Apr.-May-June, pp. 60-62. (See section 4, Cornea and Sclera.)

Blegvad, Olaf. **Myxoma of the orbit.** *Acta Ophth.*, 1944, v. 22, pt. 2, pp. 131-140.

The five cases reported in the literature are briefly reviewed and an additional one is described clinically and histologically. In the course of six years a woman, 29 years of age, developed a hyperopia of eight diopters in the left eye and a tumor the size of a walnut in the temporal side of the left orbit. The symptoms, in addition to the refractive changes were exophthalmos, impaired ocular motility, loss of vision, pain in the eye, and a stellate folding of the retina, with the macula as a center. The retina in this area was edematous, and the author attributes the folding to pressure by the tumor. Five months after the surgical removal of the neoplasm the exophthalmos subsided, the ocular motility was restored, but the retinal folding, impaired visual acuity, and hypermetropia were still present. (4 illustrations.)

Erpf, S. F. Wirtz, M. S. and Dietz, V. H. **Plastic artificial eye program.** *U.S. Army. Amer. Jour. Ophth.*, 1946, v. 29, August, pp. 984-992. (8 figures, references.)

✓Cutler, N. L. **A basket type implant for use after enucleation.** *Arch. of Ophth.*, 1946, v. 35, Feb., pp. 71-83.

The author describes a new type of orbital implant which has been used 50 times in an Army general hospital. Following enucleation, a specially constructed basket-like implant is secured in Tenon's capsule by three sutures. The sutures are tied over a button which is forced down into the implant in such a way as to produce a depression in the socket. Both implant and button are made of Lucite (methyl methacrylate). A plastic retainer is then placed behind the lids and a moderate pressure bandage is applied. Within three weeks a special plastic artificial eye may be worn.

Actual measurements of motion were made on 20 patients in which there had been no implant, 20 with a ball implant, and 20 with the new basket implant. The average range of motion expressed in degrees for no implant was 69, for the ball implant 74, and for the basket implant 109. It was found that with the basket implant and a new type of prothesis there was more instantaneous movement and a wider range of action. Thirteen illustrations depict the operative technique. John C. Long.

✓García Nocito, P. F., and Zubillaga, J. B. **Frost-Lang operation.** *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Oct., p. 513.

After discussing the different techniques for enucleation with implant, the authors express their preference for the Frost-Lang operation. They used vitallium and lucite implants with very good results. The article is illustrated. Plinio Montalván.

Givner, Isadore. **Reconstruction of the floor of the orbit.** *Amer. Jour.*

Ophth., 1946, v. 29, August, pp. 1010-1012. (3 figures, references.)

Godtfredsen, Erik. **Orbital complications following operations on the paranasal sinuses.** *Acta Ophth.*, 1944, v. 22, pt. 4, pp. 401-418.

The conclusions are reached from a study of 42 cases gathered from the literature and eight cases in the author's personal experience. The tabulated data show that in surgery of the frontal and maxillary sinuses orbital complications are rare and insignificant. They are more frequent and severe after surgery of the ethmoid labyrinth, usually in the form of orbital hematoma or optic nerve lesions. At the onset of orbital complications the eyegrounds should be examined; the appearance of orbital stasis is an indication for orbitotomy and orbital drainage, which if performed promptly will restore vision. Unless this is done within 24 hours of the onset of an optic nerve lesion the prognosis is poor. (4 illustrations.) Ray K. Daily.

Ingalls, R. G. **Penetrating wounds of the cornea with hypopyon treated with penicillin.** *Amer. Jour. Ophth.*, 1946, v. 29, Sept., pp. 1152-1154. (2 figures.)

Jaquelin, A., Turiaf, J. D. **Atypical ocular tuberculosis; tuberculin tests; and tuberculin therapy.** *Ann. d'Ocul.*, 1945, v. 178, Nov., pp. 514-527.

Atypical tuberculous lesions are relatively frequent not only in the eye but also in the joints, skin, bronchi, and nervous system. The injection of tuberculin in sufficient amount will produce aggravation of usually mild chronic lesions in these parts if they are tuberculotoxic in origin. Their frequent association leads the authors to consider them as a syndrome, char-

acterized by pathologic lesions found in tuberculosis but without the presence of the specific organism. The subcutaneous injection of tuberculin is advised for diagnosis and treatment. For diagnostic purposes, 0.5 mg. is injected subcutaneously. If no reaction occurs in four days 1 mg. is given, and if necessary 5 mg. is injected four days later. In treatment with tuberculin one strives to avoid a general or local reaction. Of 48 patients, 26 were considered cured, that is the process was inactive for more than two years. There were 13 cases of iridocyclitis, 6 of iritis, 3 of sclerokeratitis, 2 of keratoconjunctivites, 1 of iridochoroiditis, 1 of uveitis. Among the complete failures were 3 cases of iridocyclitis, 2 of sclerokeratitis, 1 of iritis, 1 of iridochoroiditis, 1 of chorioretinitis, and 1 of choroiditis. In thousands of injections only two fatalities could possibly be attributed to tuberculin injections. In a man, 63 years of age, fatal meningitis occurred shortly after the injections were begun. In another patient, severe hemoptysis followed the injection of tuberculin.

Jensen, C. F. D. **Tantalum enucleation implant.** *Amer. Jour. Ophth.*, 1946, v. 29, Sept., pp. 1151-1152. (3 figures, references.)

King, E. F., and Samuel, E. **Fractures of the orbit.** *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, pp. 134-154.

The authors present the classification of fractures of the face of McIndoe and describe several types of fractures of the nasomaxillary complex or central bony mass. In an upper fracture the line traverses the root of the nose and in the orbit divides the roof from the inner and outer walls. The facial bones are separated from the cranium and

severe intracranial hemorrhage ensues. In a middle fracture the line traverses the nasal bones, the inner wall and floor of orbit to the infraorbital foramen, and the anterior face of the maxilla to the pterygo-mandibular fossa. The detached bony mass tends to be displaced backwards and a flattened dishface results.

Another type of fracture which is not frequent is a downward displacement of part of the orbital floor, unassociated with any damage to the margin of the orbit or surrounding facial bones.

Damage to the eye must be given first place in diagnosis and treatment. Hemorrhage that appears in the lids some hours after an injury suggests an underlying fracture. Surgical emphysema indicates communication with the ethmoid cells or antrum. It increases on blowing the nose and usually subsides in a few hours. Loss of continuity of the orbital margin with local tenderness indicates an orbital fracture. Proptosis is due to displacement of the globe by bony fragments or hemorrhage within the cone of muscles. When it occurs some weeks or months later it indicates an arteriovenous aneurysm, usually of the cavernous sinus and occasionally of the orbital vessels. It is accompanied by a bruit, pulsation of the globe, and congestion of the veins of the lids and retina. Proptosis may lead to exposure keratitis. Endophthalmos and downward displacement of the globe can be due to depression of the orbital floor if there is an associated rupture of the suspensory ligament of Lockwood. An intractable sinus may result from a foreign body. Anesthesia in the areas of distribution of the infraorbital or other branches of the trigeminal nerve also suggests fracture. Traumatic stricture of the

nasolacrimal duct with secondary infection of the sac may occur in fractures of the nasomaxillary complex.

Pressure on the nerve in the optic canal, hemorrhages into the nerve sheath, traumatic arachnoiditis, and lesions of the vessels that supply the optic nerve result in reduction of vision. Diplopia is the most important ophthalmic sequel and is often the dominating permanent disability.

In the early stages treatment consists of reduction of the bony deformities. Later little more than cosmetic improvement by the insertion of subcutaneous bone-grafts is possible. The defective movement of the globe usually can be corrected surgically only if it is due to paralysis of individual muscles. (12 figures.)

Beulah Cushman.

Lech Junior. **Plastic operations on the orbital cavity.** Arquivos do Instituto Penido Burnier, 1945, v. 7, Dec., pp. 30-56.

The paper deals with correction of the orbital cavity for readaptation of prosthesis. The subject is covered under the headings of bloodless dilatation, topographic anomalies, absence of lower cul-de-sac, subtotal and total retractions of the cavity, and conclusion. The methods of a number of authors are described and illustrated. (23 illustrations, bibliography.)

W. H. Crisp.

Mata Lopez, Pedro. **Concerning a form of ocular sympathalgia.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, May, pp. 371-377.

There are certain patients who complain of dull pain about the orbits that is sometimes associated with close work but not dependent upon it, vaso-

motor disturbances of the anterior pole of the eye of the sympathetic type, slight photophobia, and at times slight rhinorrhea. The syndrome seems to have features in common with the syndrome of Sluder and possibly should be included with it. Phenolization of the sphenopalatine ganglion has been found to produce a rapid and lasting cure.

J. Wesley McKinley.

Moras, P. V., Deschamps, J. L., and Ardouin, M. Diagnostic remarks and therapeutics of ocular tuberculosis. *Ann. d'Ocul.*, 1945, v. 178, Nov., pp. 490-513.

In a detailed study of 30 patients, 10 were male, 20 female, and more than half under 25 years of age. In one half of the patients only one eye was affected. The following conditions other than simple phlyctenulosis, were observed: kerato-conjunctivitis, recurrent phlyctenular type, 2; interstitial keratitis, nodular type, 1; sclerokeratitis, 7; iritis and iridocyclitis (anterior uveitis) 10; hyalitis and diffuse choroiditis (posterior uveitis) 6; circumscribed choroiditis 2; tuberculous periphlebitis 1; recurrent hemorrhage 1. In several patients the following sequence was noted: phlyctenulosis, sclerokeratitis, iritis, anterior uveitis, and posterior uveitis. In the thirty patients studied not one case of classical ocular tuberculosis was observed. Twenty-five percent of the patients had tuberculous antecedents. A positive cutaneous tuberculin reaction was considered of value only in the very young. Radiologic examination of the thorax, done in every patient, frequently did not show active lesions concurrent with the ocular lesions, but did show scars and calcification. Among the clinical manifestations observed were recurrences

after fatigue and healing after rest and other hygienic measures. Scleral involvement in phlyctenular recurrences, slight corneal vascularization, a chalky appearance of the cornea, segmentary or annular corneal lesions were frequently observed. In iridocyclitis common manifestations were hemorrhage into the iris, large gray adherent fibrinous exudates, and early depigmentation of the iris. Secondary glaucoma occurred in three of ten eyes with uveitis. Tuberculous iridocyclitis may develop rapidly after a sudden onset and may improve after injections of mercury cyanide. In choroiditis changes of pigmentation are slight, delayed, and limited to the margins of the lesion. Of little value were the Verne resorcin reaction, globular sedimentation, and the Besredka complement reaction. The tuberculin test is considered final, quantitatively and qualitatively. One, two or three subcutaneous injections of tuberculin are used depending on the amount and character of the reaction. The first injection consists of 1 cc. of a solution containing 1 mg. of tuberculin. If negative, in three days a second injection of 3 mg. in similar dilution is administered and in five days 5 mg. is injected. The reactions may be local, general, or ocular. The last consists of increased sensitiveness, photophobia, slight diminution of vision, increased injection, increased hemorrhage, and hypertension. If intelligently used, permanent ill effects are rare. A positive reaction is definitely diagnostic of a tuberculous etiology and a negative reaction rules it out with equal certainty. The treatment advised is tuberculin in small but increasing doses with avoidance of a focal or general reaction. Six months may be required for appreciable im-

provement and twelve months for a cure. Tuberculin treatment is contraindicated in advanced or hemorrhagic pulmonary tuberculosis. Residence in altitudes more than 5000 feet above sea level is considered an important adjunct to other treatment. Among auxiliary treatments considered worthy of further study are local light therapy, auto-hemotherapy, and the prolonged injection of vitamin D and calcium. A detailed analysis of the progress and treatment of the 30 patients studied is reported.

Chas. A. Bahn.

Quintana, Juan. **Orbital mixoma.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, May, pp. 346-351.

A pure orbital mixoma is rare. Such a tumor was found in the anterior inferotemporal position of the orbit. It caused exophthalmos with displacement of the globe upward and inward. Extirpation was complete without recurrence in six months.

J. Wesley McKinley.

Rønne, Gerhard. **Local treatment of intrabulbar infections. The clinical and histological picture of staphylococcus infection.** Acta Ophth., 1944, v. 22, pt. 1, pp. 105-116.

A clinical and histological description of the course of experimental intrabulbar staphylococcus infection, into the anterior chamber, and into the vitreous is presented. Fifty bacteria of the strain used by the author injected into the vitreous were sufficient to produce perforation of the eyeball within four days. The symptoms, which appeared on the second day, were exophthalmos, corneal edema, and conjunctival injection and secretion. The histological picture is characterized by a primary reaction in the retina and

ciliary body; choroidal changes appear later, and the anterior ocular segment remains free of bacteria for a long time.

Rudemann, A. D. **Plastic eye implant.** Amer. Jour. Ophth., 1946, v. 29, August, pp. 947-952. (11 figures.)

Rundle, F. F. **Observations on a case of orbital varix.** Clinical Science, 1945, v. 5, Dec., pp. 139-144.

This condition produces a characteristic clinical syndrome including the dramatic phenomenon of transient severe proptosis. A man, 45 years of age, complained of a protrusion of his right eye on stooping. The position of the right eye in its orbit varied in the different positions of the body whereas the left eye remained in the same position at all times. The Hertel exophthalmometer was used for measurements. When the cervical veins were compressed by means of a pneumatic cuff placed around the neck, the exophthalmos reached a maximum of 18 mm. At this point the eyeball moved 2 mm. laterally but not upwards or downwards. Recession proceeded rapidly after release of the compression. The visual acuity and field, fundus, pupil, and pupillary reactions were normal. When maximal compression was maintained for five to eight seconds the eye became blind, but vision returned to normal ten seconds after compression was released. Distinct pulsation of the globe, synchronous with the carotid pulse, occurred when the bulb was fully protruded.

Francis M. Crage.

Rundle, F. F., and Wilson, C. W. **Development and course of exophthalmos and ophthalmoplegia in Graves'**

disease with special reference to the effect of thyroidectomy. *Clinical Science*, 1945, v. 5, Dec., pp. 177-194.

Measurements provide no support for the claim that exophthalmos may develop abruptly, even over night, and that it may vary greatly from day to day. Widening of the palpebral fissure from lid retraction may at times be rapid and create the illusion of increased exophthalmos. Measurements of ocular prominence were made with Hertel's exophthalmometer, modified by the inclusion of a central stop to give greater accuracy. The vertometer measured the range of elevation.

Stages of ingravescence and remission occur in the course of exophthalmos and related eye signs in Graves' disease. The former is called the dynamic and the latter the static phase. The dynamic precedes the static phase.

The exophthalmos develops at the rate of 0.5 mm. per month with a concomitant development of paralysis of elevation. The latter loses four to five degrees for each millimeter of protrusion. Exophthalmos and ophthalmoplegia are slower and less complete in their progressive stage.

The position of the globe depends on the volume of the orbital tissues. The orbital change is a true growth of tissue and the resultant exophthalmos, as indicated by the curves is of the same order in all cases, even after thyroidectomy. The increased exophthalmos after thyroidectomy is not due to excess thyroid hormone. It is merely evidence that the patient was probably in the dynamic phase of the disease. The orbital tissue growth seems to be produced by some nonthyroid hormone. After thyroidectomy for thyrotoxicosis, the exophthalmos and range of elevation of the eye showed little

change. When a slight increase in protrusion occurred it could be ascribed to recovery from loss of weight.

Francis M. Crage.

Wheeler, Maynard. **Exophthalmos caused by eosinophilic granuloma of bone.** *Amer. Jour. Ophth.*, 1946, v. 29, August, pp. 980-983. (2 figures, bibliography.)

Wolff, Eugene. **Hyaline bodies in the intraocular fluids and tissues.** *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, p. 179.

The author describes hyaline-like bodies that are found in the intraocular fluids and tissues and are derived from the blood. Some called hemoglobin bodies, stain bright pink with eosin and are usually formed by a clumping together of about 25 red cells. They occur in the aqueous and vitreous in acute and subacute inflammations associated with hemorrhage. They are not nucleated but may engulf a cell, a nucleus, or any solid matter such as pigment.

Fibrin bodies typically are rounded bodies. They may be much smaller than a red cell or four to five times as

large. They may not be strictly circular but their margin is not as irregular as that of a hemoglobin body. The bodies may settle on the internal limiting membrane and become hemispherical. In early stages they stain pink, as they grow older they take on the blue (basophilic) stain and eventually they may become calcified. They may be surrounded by cells. They are more often seen in acute and subacute inflammations than in chronic.

The author distinguishes both types from Russell bodies which are hyaline spherules formed in chronic inflammatory conditions only in the presence of plasma cells. In the eye they are found in the iris, ciliary body, choroid, retina, and conjunctiva. Beulah Cushman.

Woods, A. C. **The ocular changes of primary diffuse toxic goiter.** *Medicine*, 1946, v. 25, May, pp. 113-154.

This comprehensive review discusses, in great detail, the usually noted ocular changes of primary toxic goiter. In the first section, all of the lid signs are described, and the author explains each one, in terms of the relationships between relaxation of the orbicularis muscle, overaction of the levator muscle and increased tone of the palpebral smooth musculature. The last mentioned factor is a logical one, in view of other evidences of sympathicotonia in toxic goiter.

Under the heading of external ocular changes, the author discusses weakness of convergence (Moebius' sign), abnormal pigmentation of the skin of the lids (Jellinek's sign), adrenalin-sensitized pupils (Loewi's sign), and excessive lacrimation.

Two types of patients with extraocular muscle palsies are described. The patients in the first group have

isolated or multiple pareses, with no definite pattern of involvement. These occur with exophthalmos, and disappear when the thyrotoxicosis is controlled. Organic changes analogous to those of myasthenia gravis are sometimes found in these muscles. However, there is no favorable response to prostigmine. In the other type ocular-muscle palsies occur in "malignant exophthalmos," or "exophthalmic ophthalmoplegia." The muscle changes progress even after thyroidectomy. The muscles show hypertrophic myositis, fibrosis and edema. This condition has been related to postoperative changes in pituitary function, and treatment must include thyroxin and iodine.

Exophthalmos is seen in 65 percent of patients with primary diffuse toxic goitre. Reports are cited to indicate that the exophthalmos does not regress after the thyrotoxicosis is controlled. The pathogenesis of the exophthalmos is discussed and the importance of the following factors is evaluated.

Hypertrophy of orbital contents, particularly orbital fat is considered important. Relaxation of the rectus muscles, allowing the eye and orbital contents to protrude is probably not an important factor, since the role of the obliques is not satisfactorily explained. The importance of contraction of smooth muscle of the orbit is difficult to accept, since the orbital smooth muscle is vestigial in man. Edema of the orbital contents has been substantiated as a factor in exophthalmos. Orbital vasodilatation has not been proved to be a causative factor. Degenerative myositis, with increase in muscle size, can be at best only an inconstant cause of exophthalmos, since it is not uniformly present.

The action of the anterior pituitary

hormone probably plays a part. The work of Mulvany is discussed. The author concludes that although there appears to be a relationship between the exophthalmos and the anterior pituitary, its exact nature is as yet unknown.

EYELIDS AND LACRIMAL APPARATUS

Cristini, G. Myoblastoma of the lid. *Rassegna Ital. d'Ottal.*, 1946, v. 15, May-June, pp. 207-223.

The dual nature of muscular tissue gives rise to the terms of leiomyoma and rhabdomyoma, depending upon whether the newgrowth is composed of smooth or striated muscle. The tumor described by Cristini was found in the lower lid of a woman 57 years of age and was classified as myoblastoma. It is the sixth one to be reported. The tumor develops slowly and insidiously and presents no characteristic clinical picture. Histologically the case is interesting because of the great variety of cell types and the complexity of structural features. Various phases of differentiation and maturation of the primitive myoblastoma to the fibrocellular striated muscle are seen. (5 figures, bibliography.)

Eugene M. Blake.

Dobyns, B. M. Studies on exophthalmos produced by thyrotropic hormone. *Surg., Gynec., and Obst.*, 1946, v. 82, March, pp. 290-300, May, pp. 609-617, June, pp. 717-722.

This study was undertaken to investigate the changes in the prominence of the eyes induced by the administration of various preparations of thyrotropic hormone and to correlate the exophthalmos with various tissue

changes. In normal guinea pigs, thyroidectomy caused an increase in the prominence of the eyes. The intercorneal distance was used as a measurement of exophthalmos. At varying time intervals after the operation the following pituitary preparations were given and the exophthalmos measured. After antuitrin T definite exophthalmos occurred. After the purified thyrotropic product hyperplasia was noted but little or no exophthalmos. The crude extract produced an exophthalmos greater than the last drug but less than the first, and it also caused thyroid hyperplasia. The specific metabolic principle did not produce exophthalmos. Half the animals were castrated, which did not influence the development of exophthalmos. The antuitrin T produced gross and microscopic changes in the connective tissue in the orbit and elsewhere in the body. The fat deposits were depleted and partially replaced by a gelatinous material. Plasma fat and blood acetones were elevated and there was a polymorphonuclear leucocytosis. Skeletal and cardiac muscle fibres lost their striations and were found to contain multitudes of fat droplets. The theoretical and clinical significance of the micro-pathologic changes are discussed. (17 illustrations, 4 tables, references.)

Bennett W. Muir.

Grönvall, Herman. A case of supernumerary caruncula lacrimalis. *Acta Ophth.*, 1944, v. 22, pt. 2, pp. 158-165.

A case of supernumerary caruncle in a seven-year-old child is reported. Because it apparently caused a sensation of chafing in the eyes, and consequent grimacing it was excised and found to have the histologic structure of a normal caruncle. A tabulated review of seven cases reported in the literature

is given and the pathogenesis discussed. (3 illustrations.) Ray K. Daily.

Lodge, W. O. **Observations on the eyelids.** J. Internat. Coll. Surgeons, 1946, v. 9, May-June, pp. 383-378.

The author mentions some forty affections of the lids. Spastic entropion may sometimes be cured by painting the lower lids with colodion. For paralytic ectropion he exposes the internal palpebral ligament and the frontal process of the zygomatic bone. A 0.003-inch tantalum wire is inserted horizontally through the lower lid and attached to the areas exposed. He uses a similar wire in the Motais and Hess types of operation for ptosis. (4 figures.)

I. E. Gaynon.

McArthur, G. A. D. **Some notes on West's operation (endonasal dacryocystostomy).** Med. Jour. Australia, 1946, v. 1, April 13, pp. 508-510.

The author describes his technique of endonasal dacryocystostomy. He removes a small portion of the medial wall of the sac through the frontal process of the maxilla. Failure occurs when the sac is too small, an inadequate opening is made, and if there is stenosis of the junction of the canaliculus and sac. Of 42 operations 35 were successful.

I. E. Gaynon.

Stenbeck, Anna. **A follow-up of dacryocystorhinostomies.** Acta Ophth., 1944, v. 22, pt. 1, pp. 27-35.

This is an analysis of the surgical experience at the Sabbatsberg Hospital during the five-year period from 1936 to 1941. One hundred and seventy external operations were performed, of which 134 could be followed. In 116 cases the lacrimal passages were patent on irrigation, and 18 were impermeable. Most of the patients with patent

lacrimal passages had no symptoms. A few had epiphora only in the wind. Five had constant epiphora; in two of these the lower canaliculus was obstructed before the operation; one had a hyperplastic rhinitis, and in two the continuous epiphora in spite of patency of the lacrimal passages could not be explained. Of the 18 cases impermeable to irrigation 15 were normal when discharged, 3 developed obstruction shortly, 6 after two months, and 5 about one and one half years after the operation. In one patient the canal was patent for five years, when conjunctivitis, followed by an infection in the sac, resulted in an obstruction with dense tissue. In three patients the data on the recurrence of symptoms could not be established. Three patients were operated upon a second time, one externally and two intranasally; the connective tissue blocking the lacrimonasal opening was removed. A division of the material into four groups shows satisfactory results in 79.4% of stenosis, 87.8% of dacryocystitis, 73% of phlegmons, and 33.3% of pericystitis. It appears that the prognosis is best in dilated sacs, regardless of their content. Because the immediate post-operative results are better than the final, it is important to follow the patients for some time.

Ray K. Daily.

Svoboda, J. **Surgical treatment of lacerations of the lower lacrimal canals.** Lekarske Listy, 1946, v. 1, July 1, pp. 307-308.

Lacerations of the lower lacrimal canaliculus were corrected with the aid of the following operation in 53 patients. A probe-like wire is passed through the disrupted canal, after sutures have been placed in the conjunctiva but not tied. Then the edges of the laceration are stitched together

and the knots tied. It is important that the wire enters the nasolacrimal duct. The wire is retracted gradually during the postoperative period.

O. Felsenfeld.

Thygeson, Phillips. **The etiology and treatment of blepharitis: a study in military personnel.** *Military Surg.*, 1946, v. 98, March, pp. 191-203.

Blepharitis was the most common external eye infection seen in military personnel. Laboratory and clinical studies of 350 cases of blepharitis indicate that the three important types are the staphylococcic, the seborrhoeic blepharitis, and the diplobacillary. Staphylococcic blepharitis is often unilateral, and is often associated with chalazion, hordeolum, and ulceration. It is characterized by small hard scales, which are tenacious and difficult to remove. An associated keratoconjunctivitis is almost the rule. Temporary or permanent loss of cilia, and associated otitis externa, impetigo, sycosis barbe and acne vulgaris are common. There is burning, itching, and photophobia.

With seborrhoeic blepharitis, there is seborrhea capitis, and usually an associated seborrhoeic dermatitis of brow and ears, the lesion is always bilateral, nonulcerative, and squamous, the scales are greasy and easy to rub off, and associated conjunctivitis is minimal if present. There are no complicating inflammations. The skin gives evidence of increased seborrhea, discomfort is minimal.

Diplobacillary blepharitis is characterized by maceration of the skin at the inner and outer canthus, and associated conjunctivitis. The infection is superficial, there is no ulceration, and no inflammation of the Meibomian glands.

The finding of budding yeast forms,

pityrosporum ovale, was considered diagnostic of seborrhoeic blepharitis. Routine bromoscopic examinations of the lid margin in chronic conjunctivitis revealed a high incidence of mild and subclinical blepharitis, usually staphylococcic. There is no evidence that vitamin deficiency, refractive error or allergy play significant roles.

I. E. Gaynon.

Torti, M. **Congenital lacrymal fistula.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, no. 1 and 2, p. 69.

Torti describes two cases of unilateral fistula of the lacrymal sac, one of which was definitely of congenital origin, the other probably inflammatory in nature. His conclusions are based upon histological studies of the excised tissue. Congenital fistula is caused by a supernumerary canaliculus and arises at the same period of development as the canaliculi. Godtfredsen, Erik. **Ophthalmologic and neurologic symptoms of malignant naso-pharyngeal tumors.** *Acta Ophth.*, 1944, supplement 22, pp. 373.

This exhaustive monograph is based on a review of the literature and on a study of 454 case histories from the largest radiologic clinics of Denmark and Sweden, during the period from 1927 to 1942. The clinical symptoms are described in great detail. Of interest to the ophthalmologist are the patients with ophthalmoneurologic symptoms, which constitute 38 percent of this material. Usually these symptoms appear early if they appear at all. The nerves most frequently involved were the fifth cranial nerve and the eye nerves, separately or jointly. Half of the ophthalmoneurologic patients presented purely ophthalmologic symptoms, such as muscle paralysis, optic tract lesion, exophthalmos, and Horner's syndrome. These findings indicate that a malignant naso-pharyngeal tumor should be suspected in the presence of these symptoms, even if local nasopharyngeal symptoms are absent. In these patients there was an average period of 11 months between the onset of symptoms and a correct diagnosis. An exhaustive examination of the nasopharynx should lead to an earlier diagnosis, earlier institution of proper treat-

ment, and a better prognosis. An analysis of microscopic preparations in 458 cases reveals a difference between those with and without ophthalmoneurologic symptoms. The former contain a relatively greater number of squamous-cell carcinomas and cylindromas, and a smaller number of plasmocytomas and lymphosarcomas than the latter.

The therapeutic results show that sarcomas and lympho-epitheliomas are fairly radio-sensitive, and that with modern radiation therapy 22 percent of patients were free from symptom for five years, and three fourths of all become free from symptom after treatment. (53 illustrations, 30 tables.)

Ray K. Daily.

Penido Burnier and Salles Monteiro. **Teratoma of the orbit.** *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 114-128.

The authors found the subject dealt with merely in articles of the French and American encyclopedias of ophthalmology and in a few scattered articles in ophthalmologic reviews. They report the case of a two-months-old female child born at term, of normal birth. Three previous pregnancies had been normal and had been completed at term. There had been one spontaneous abortion at a few months, preceding the last completed pregnancy. The mother reported that the child had been born with the orbital tumor practically of the same size as it manifested at the age of two months. X-ray examination showed a great increase in size of the left orbit. Puncture at two different levels was negative. The puncture needle traversed trabecular areas sometimes of clayey consistency. After making the differential diagnosis from

hernias of cranial content, the tumor was successfully excised. It measured 6.2 by 6.0 by 4.5 cm., and weighed 92 gm. (10 illustrations, including 4 photomicrographs, references.)

INJURIES

Alvis, Bennett Y. The use of the Berman locator in removal of intraocular foreign bodies. South. Med. Jour., 1946, v. 39, Feb., p. 125.

This instrument has helped to differentiate a magnetic from a non-magnetic foreign body, to locate a magnetic foreign body, and to follow its changing position during the course of its removal.

Seven cases are briefly described and discussed. Important surgical details are mentioned and the exact localization of the foreign body is reported, at times with an accuracy so great as to obviate the need to introduce the magnet's tip into the vitreous.

The size of the foreign body and its distance from the locator has a definite influence on the latter's response. Posteriorly located small foreign bodies bring a response if the globe is rotated

so as to shorten the distance between the locator and the foreign body.

F. M. Crage.

Bertotto, E. V. *Symblepharon with serious effect on motility*. Anales Argentinos de Oft., 1945, v. 6, July-Aug.-Sept., pp. 98-100.

After an injury to the left eye by a machine-screw, conjunctival synechiae formed which prevented movement of the eye inward and upward. As a result, diplopia manifested itself in these directions of gaze. After two operations to relieve the symblepharon the diplopia disappeared and normal ocular motility returned. Edward Saskin.

Broendstrup, Poul. Two cases of temporary siderosis bulbi with spontaneous resorption and without impairment of function. Acta Ophth., 1944, v. 22, pt. 3, pp. 311-316.

In the first patient a small intraocular foreign body was discovered two years after the injury. The patient complained of failing vision and discoloration of the iris. There was incipient cataract and siderosis of the iris. The foreign body was not removed. The siderosis progressed for a few months, and then gradually receded until six years later when the color of the iris had become normal. Eleven years after the first examination the foreign body could not be demonstrated roentgenoscopically. The second patient, a man, 19 years of age, presented unmistakable clinical signs of an ocular perforation and pronounced siderosis of the iris without a history of trauma and without a demonstrable foreign body. In the course of 18 months he developed a mature cataract which was successfully needled. Fourteen years later all evidence of siderosis had disappeared.

It is pointed out that the result might be better if small intraocular foreign bodies were left to spontaneous absorption.

King, E. F., and Samuel, E. Fractures of the orbit. *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, pp. 134-154. (See Section 13, Eyeball and orbit.)

Luz, B. da, and Sebas, S. R. Foreign body tolerated for eleven years. *Rev. Brasileira de Oft.*, 1946, 4th yr. June, no. 4, pp. 313-316.

The patient was a mechanic aged 40 years, the sight of whose right eye had been lost in consequence of penetration of the eye by a fragment of metal 11 years previously. He had

many periodic attacks of ocular and periorbital pain, varying in intensity. There was no light perception. In the enucleated eye the metallic foreign body was found embedded in the sclera 3 mm. behind the equator of the eye. The lens was absent, probably having been removed in an earlier operation to which the patient made vague reference. (References.) W. H. Crisp.

Marner, Else. A case of ocular chalcosis with spontaneous resorption of the copper and disappearance of chalcosis. *Acta Ophth.*, 1945, v. 23, pt. 2, pp. 171-174.

This is a follow-up report of a case reported by Kjerrumgaard in 1941. A 10-year-old boy had both eyes injured in 1937 by the explosion of a percussion cap. X-ray examination revealed two small metallic foreign bodies in each eye. Three years after the injury there was bilateral chalcosis. Eight years after the injury no foreign bodies could be demonstrated in the left eye by X ray, and the chalcosis in that eye had practically disappeared; there were only faint traces of the previously found disk-shaped central opacity on the anterior surface of the lens. The chalcosis on the right side persisted, but one foreign body was no longer visible. Ray K. Daily.

Pinkerton, O. D. Traumatic liporrhagia retinalis. *Arch. of Ophth.*, 1946, v. 35, Feb., pp. 176-178.

The history of a case of traumatic liporrhagia retinalis or Purtscher's disease in an 11-year-old Filipino boy is presented. The boy was struck by a vehicle. The injury consisted of a severe lacerated wound of the left temporal and frontal areas and the left external canthus, compound, comminuted, complete fracture of the left

zygoma, and contusions of both sides of the face, the chest, and the upper portion of the abdomen. Within six hours the vision of the right eye was limited to perception of light peripherally. A massive yellow extravasation with hemorrhages was observed in the fundus. Within a month there was complete absorption of the exudate and hemorrhage except for a small amount between the nerve head and macula. A marked pallor of the nerve developed. Vision was limited to counting fingers at three to four feet in the temporal and superior fields only. Abscess of the lung developed at a late date.

Swanson, C. A. and Stewart, R. A. Causes of uniocular and binocular blindness in the U. S. Navy and U. S. Marine Corps in World War II. *Sight-Saving Review*, 1946, v. 16, Spring, pp. 36-46.

The treatment of ocular injuries during World War II were characterized by improved care mainly because of chemotherapy. Of 119 cases of bilateral blindness, 84 resulted from trauma, and 35 from medical causes. Methyl alcohol poisoning was the cause in 19 of the latter. Of 640 cases of unilateral blindness, 464 resulted from trauma. Two-thirds of the intraocular foreign bodies were magnetic. The Berman locator is useful in determining this fact. Foreign bodies up to 2 mm. in diameter usually leave a useful eye. Sympathetic ophthalmia occurred five times after removal of intraocular foreign bodies. I. E. Gaynon.

SYSTEMIC DISEASES AND
PARASITES

Arroyo, Manuel. **Onchocercosis and its ocular complications.** *Rev. Brasileira de Oft.*, 1946, 4th yr., June, No. 4, pp. 285-295.

The author summarizes the first classical report of a case as given by Rodolfo Robles, including the following symptoms: reddening of the conjunctiva; iritis; the formerly brilliant and transparent cornea becoming dull and without gloss; tiny leukomas (as though the patient had suffered from an ulcerative keratitis); constant headache and periorbital pain, and marked diminution of visual acuity. In honor of the distinguished ophthalmologist referred to, who died recently, the present author urges that the disease should be known as Robles's disease.

W. H. Crisp.

Arumi, J. **Subconjunctival cysticercus.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, May, pp. 339-345.

A case of a cyst that was excised and studied histologically is reported.

J. Wesley McKinney.

Brueckner, R. **A case of Sjögren's syndrome, successfully treated with Perandren.** *Ophthalmologica*, 1945, v. 110, July-Aug., pp. 37-42. (See Section 6, Cornea and sclera.)

Cassady, J. V. **Uveal blastomycosis.** *Arch. of Ophth.* 1946, v. 35, Feb., pp. 84-97.

A 64-year-old white man was first seen because of polyarthritis and

cutaneous lesions. During the course of severe and multiple systemic manifestations, a uveitis developed in the right eye. Posterior synechiae were present and a yellowish, tubercle-like nodule was seen at the pupillary margin of the iris and another at the base. Biopsy and culture of material from the cutaneous lesions yielded a fungus identified as *Candida parapsilosis*. Attempts to culture this organism from the aqueous were unsuccessful. The patient's condition grew worse and he died approximately one year after the onset of the joint symptoms. Autopsy showed extensive blastomycotic lesions in the skin, lungs, prostate, kidneys, bones, and eyes. Histologic study of the eye showed tubercles in the deep corneal abscesses, areas of necrosis, lymphocytes, plasma cells, epithelioid cells, and giant cells. Giant cells which had engulfed the double-contoured bodies of fungus, some of which were budding, were found throughout the mass in great numbers..

Should eye changes become apparent during the course of endogenous blastomycosis (Gilchrist's disease) the author suggests the withdrawal of the plasmoid intraocular fluid for cytologic examination and culture. (11 illustration.)

John C. Long.

Contino, F. **Surgical treatment of subretinal cysticercus.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, May-June, pp. 165-181.

Since all attempts to destroy an intraocular cysticercus by medical means appear to be useless the treatment must be surgical. After reviewing all the methods employed to destroy the parasite within the eye, the author describes two eyes in which he succeeded in killing the cysticercus by means of diathermy coagulation with the Weve

technic. The treatment permitted the retention of the globe but vision was almost nil. (2 figures, bibliography.)

Eugene M. Blake.

Davenport, R. C. Ocular psychoneuroses. *Trans. Ophth. Soc. United Kingdom*, 1944, v. 64, p. 24.

The incidence of ocular psychoneurosis is difficult to estimate but patients may be roughly grouped in three divisions: those with an obvious organic defect that causes the symptoms; those with an inadequate organic basis for their troubles; and an intermediate group in which the patients have an organic lesion upon which an element of neurosis is overlaid.

The large majority of patients present enough of their personality for the ophthalmologist to make adequate judgment before he proceeds to treatment. Much of the judgment may be made as the history of the complaint is given.

The large majority of patients have hysteria or one of the anxiety states and squints afford a wide field for the assessment of the psychopathic factor.

A number of functionally blind were received after the retreat from Flanders and most of them recovered their vision after rest and reassurance, but night terrors persisted. Of four others sent to St. Dunstan's Hospital, three had one seeing eye and the fourth a large error of refraction. Conscious malingering was rarely found.

The author urges the importance of assessing the psychological factor in all eye patients.

Beulah Cushman.

Doggart, J. H. Ocular psychoneurosis. *Trans. Ophth. Soc. United Kingdom*, 1944, v. 64, p. 29.

The psychoneurotic patient with his lowered threshold for anxiety often

collapses with panic at the mere thought of failing sight; and fear, once it has gripped him, may be aggravated by the many menacing advertisements.

The commonest complaints in ocular psychoneurosis are failing vision, spots or flashes of light, intolerance of glares, double vision and difficulty in focusing, transient blurring, and aching of the eyes.

The author found that elaborate traps for the malingerers seldom justified the time expended, as most malingerers are stupid enough to give themselves away. The borderline between conscious pretense and psychoneurotic inhibition cannot always be established, and in any event no disciplinary action can be taken on a charge of foxing over test-types.

He concluded with Tostevin that ocular defects were seldom the primary cause of failure in air cadets. The author also believes that the correlation of the different branches of medicine which is generally desirable is particularly needed between neuropsychiatry and ophthalmology. The final disposal of serious problems should be left to the neuropsychiatrist.

Beulah Cushman.

Gillespie, R. D. Ocular psychoneurosis. *Trans. Ophth. Soc. United Kingdom*, 1944, v. 64, p. 41.

All the fundamental lessons of psychosomatic medicine can be applied to or deduced from functional disorders of the visual apparatus as its functions include sensation, voluntary movement, and involuntary movement of unstriated muscle.

The dependence of many ophthalmological tests upon willing co-operation of the patient gives scope for malingering but the infinite capacity of the human race for self-deception

makes the additional gift of malingering almost unnecessary.

The most used function may often be made abnormal by hysteria or anxiety neurosis. The only common hysterical disorders of eye movement, is failure to converge, based on a lack of desire to look. Failure to accommodate can also be hysterical.

Sixty-six air crews undergoing orthoptic treatment were subjected to psychiatric examinations and 40 were found to have in some degree the same characteristics that were found in air crews that broke down with frank psychoneurotic disorders.

Anxiety symptoms may arise in someone of average psychological constitution where external stress is great or motivation to fly is inadequate.

The author is not willing to go as far as some who say that the mentality of everyone who has heterophoria is abnormal. Beulah Cushman.

Haar, M. **Ophthalmomyiasis interna posterior.** Acta Ophth., 1945, v. 23, pt. 2, pp. 135-141.

The literature on 30 published cases is reviewed and a new case reported. While spending a vacation in the mountains a twelve-year-old boy developed an iridocyclitis of the right eye, and during the course of the disease a sharply circumscribed grayish white shiny body could be seen in the vitreous below and nasal to the papilla. It was interpreted as a larva of hypoderma

lineatum. The lens became dislocated. Within a year the media cleared, vision became normal, and the appearance of the larva indicated that it was being absorbed. Within that period the child had edematous swelling on the head and face, nodules on the scalp, and eosinophilia (15 percent). Spontaneous recovery, without removal of the larva is reported in one other case in the literature. Ray K. Daily.

Morgan, O. G. **Ocular psychoneurosis.** Trans. Ophth. Soc. United Kingdom, 1944, v. 64, p. 52.

The author describes several patients with self-inflicted artefact conjunctivitis who responded to psychotherapy. Beulah Cushman.

Prezidio de Figueiredo, Nicanor. **A case of ocular avitaminosis.** Rev. Brasileira de Oft., 1946, v. 4, June, pp. 317-324.

A man of 26 years, in an artillery encampment, showed chronic irritation to which the author gives the title "blepharokeratoconjunctivitis." Failure of previous modes of treatment, and marked improvement under a Brazilian vitamin preparation, convince the author that the ocular disturbance was due to deficiency in riboflavin.

W. H. Crisp.

Richards, J. M. and Romaine, H. H. **Keratoconjunctivitis sicca.** Amer. Jour. Ophth., 1946, v. 29, Sept., pp. 1121-1125. (7 figures, references.)

Rundle, F. F. and Wilson, C. W. **Development and course of exophthalmos and ophthalmoplegia in Graves' disease with special reference to the effect of thyroidectomy.** Clinical Science, 1945, v. 5, Dec., pp. 177-194. (See Section 13, Eyeball and orbit.)

Saenz Canales, José. **The vitreous body in some ocular localizations of the cysticercus.** An. de la Soc. Mexicana de Oft. etc., 1945, v. 20, April-June, p. 55.

Much of the article is taken up with a discussion of vitreous structure, and of the literature of the subject since Graefe, who in his Archiv gave an excellent description of the ophthalmoscopic appearance. The author of the present article gives a review of the ophthalmoscopic appearance in sub-retinal localization of the cysticercus, including the innumerable glistening crystals whose appearance varies with every movement of the vesicle. A little later come the spots commonly associated with the names Liebreich and Cirincione. These are roundish spots of variable size, comparable to little drops of dirty oil, or to the precipitates of

descemetitis. Pseudomembranes frequently follow. The various stages of disintegration of the vitreous are attributed by the author to inflammation, degeneration, and allergy. (Four photomicrographs, references.)

W. H. Crisp.

Sardana, M. N. **Ocular manifestations of avitaminosis in adults.** Indian Med. Gazette, 1946, v. 81, p. 188-193.

Five hundred cases of avitaminosis with ocular symptoms were observed in 1943 at the Indian Prisoners of War Hospital in Singapore under Japanese occupation. Under the circumstances the methods of diagnosis and treatment were meager. Treatment consisted of the feeding of rice polishings, rice water, red palm oil, and marmite.

Vitamin A deficiency was found in 159 patients. The chief complaints were night blindness and itching and dryness of the eyes. The cornea was insensitive in 81 percent of the patients, there were corneal ulcers in 2 percent, disciform keratitis in 2 percent, and blepharitis in 5 percent. The pupils were dilated and visual acuity was impaired.

Deficiency of vitamin B₁ was found in 220 patients. They complained of decreased vision, photophobia, and of a burning sensation. The pupils were normal in size, reacted well to light, and were sluggish in accommodation. The fields were slightly contracted and two percent of the patients had optic nerve atrophy.

The 121 patients who had deficiency of riboflavine complained of hazy vision in the sun. The pupils were slightly dilated and reacted sluggishly to light. The visual acuity was reduced, accommodation was normal, and the fields were contracted in the upper and temporal regions.

I. E. Gaynon.

Skydsgaard, Henning. **Polyarthrititis urethritica simplex with eye symptoms. (Reiter-Freunds syndrome).** *Acta Ophth.*, 1943, v. 21, pts. 1-2, pp. 107-118.

Four cases are briefly reported. The characteristic feature of this syndrome is the non-gonorrheal triad of urethritis, conjunctivitis, and arthritis. The conjunctivitis is the least conspicuous of the symptoms. This syndrome should be kept in mind when dealing with purulent conjunctivitis of unknown etiology, and in the differential diagnosis of exogenous gonorrheal conjunctivitis. Ray K. Daily.

Souza Queiroz, Leoncio de. **Ocular cysticercosis.** *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 129-150.

From 1913 to 1945, a total of 92 cases of ocular cysticercosis have been recorded in the Penido Burnier Clinic. The statistics relating to these cases are analyzed. They include subconjunctival, cysticercus of the anterior segment, of the vitreous, and subretinal. Other phases of the subject dealt with are the reaction of the complement fixation for cysticercosis, prognosis and prophylaxis, and treatment. A typical case of subretinal cysticercus in a woman of 28 years is detailed. The cyst was in the nasal sector, was located by diathermy puncture, and was extracted with very slight traumatism. Vision returned from 0.3 to normal. (12 illustrations, elaborate analytical statistical table, bibliography.)

W. H. Crisp.

Stewart, D. S. **Ocular psychoneurosis.** *Trans. Ophth. Soc. United Kingdom*, 1944, v. 64, p. 54.

The author reviewed the histories of 131 patients who complained of head-

aches in a group of 231 psychoneurotic patients. He feels that every patient consulting an oculist is in a state of "eye consciousness." To succeed in unmasking a malingerer by optical trickery is creditable in so far as it helps to exclude an organic cause for the pretended amblyopia or spastic strabismus, but to dismiss the patient harshly without further consideration is as unsuitable as to kick away the crutches from a cripple.

Beulah Cushman.

Traquair, H. M. **Ocular psychoneurosis.** *Trans. Ophth. Soc. United Kingdom*, 1944, v. 64, p. 37.

The symptoms of the psychoneurotic eye patient are characterized by inconsistency in themselves and are not justified by the physical findings.

The diagnosis and treatment go together. As the diagnostic measures are carried out they impress the patient and pave the way for successful treatment. The study of the binocular visual field and of the field of vision of each eye separately are among the most useful tests. They should be repeated at 2 M.

The author feels that the chief cause of the psychogenic visual symptoms is fear and personal maladjustment. The chief elements in treatment are explanation, distraction, encouragement and "therapeutic conversation."

Beulah Cushman.

Weskamp, C. **Ocular syphilis.** *Anales Argentinos de Oft.*, 1945, v. 6, Apr.-May-June, pp. 47-52.

The first part deals with generalities. This section is devoted to a discussion of extraocular syphilitic lesions and their therapy with arsenic, bismuth, and malaria.

The second part deals with specific

ocular syphilis. Primary optic atrophy is a result of neurosyphilis, and appears from 10 to 20 years after the initial lesion. It is frequently accompanied by the Argyll-Robertson pupil. Interstitial keratitis is the other sign that is virtually indicative of syphilis. Treatment of ocular syphilis depends upon the location of the lesion and the duration of the disease. Lesions that involve mesodermal structures in the iris, the choroid, and the sclera, respond to bismuth, arsenic, mercury. Lesions in the neural ectoderm such as optic atrophy, require fever therapy. The author describes penicillin as a new potential antiluetic measure.

Edward Saskin.

Winnicott, D. W. Ocular psychoneurosis. Trans. Ophth. Soc. United Kingdom, 1944, v. 64, p. 46.

The author gives an account of the ocular psychoneuroses of childhood. He asks for belief in the matter of the reality of feelings in a child and as an example quotes the experience of a friend whose childhood was spoilt by the remark of an eye surgeon. He told the child's mother in her presence that she has retinitis pigmentosa and would probably become blind. The child spent her childhood expecting blindness and did not begin to realize until she was 50 years of age that the surgeon was wrong. Children feel that they are the custodians of any part of their bodies and if they fail to keep their eyes healthy they feel they have failed in a trust.

Three groups of psychological symptoms are recognized: those shown by children whose personality structure is satisfactory; those that are associated with depression; and those associated with a defect of the structure of the personality.

Glasses quickly acquire a meaning to the child who wears them as they become part of the personality of the child.

Hysterical blindness is associated with guilt about seeing.

Depression in childhood is recognized as a mood and appears clinically in its form of common anxious restlessness or of a denial of depression by forced activity and liveliness. Along with this there are self destructive actions, deliberate or accidental, and also hypochondriacal worry over the body or its parts. Depression is very common among children and hypochondriacal worry joins with normal concern.

Hypochondria of the mother must be distinguished from that of the child. True reassurance comes from statement of facts.

Squint can have a purely psychological cause and the author describes three types: an external squint in which the two eyes do not work with one aim, and that is associated with a division in the personality; convergence that can be likened to thumb sucking; and a type that accompanies a phase of acute introversion.

Beulah Cushman.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Cordes, F. C. Ophthalmology's post war responsibilities and opportunities. *Jour. Amer. Med. Assoc.*, 1946, v. 131, Aug. 24, pp. 1395-1397.

A three or four year residency at a medical center is ideal. A basic course

of six or eight months followed by a year or more of carefully supervised clinical work will help to make a safe ophthalmologist. Training may also be acquired through preceptorship and association in private practice with a qualified ophthalmologist. The basic course plus supervised reading, as outlined in the home study course, is essential. A number of three-year residencies and refresher courses should be arranged for training of men from Central and South America.

I. E. Gaynon.

Harrowes, W. M. Psychological reactions in war blinded. *Brit. Med. Jour.*, 1946, no. 4464, July 26, pp. 129-130.

Forty patients were studied. All had a retrospective flattening out of a reactive depression. Thirty-five percent developed a classical tension depression characterized by fault finding, uncooperativeness, undue slowness of learning, and rejection of all suggestions. One patient over-compensated and the others gradually became stabilized.

Lech Junior. Twenty-five years of activity of the Penido Burnier Institute. *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 5-29.

With ample statistics, and 12 architectural and personal photographs, this 25-page article reviews the history of the institution.

W. H. Crisp.

Pinson, E., and Chapanis, A. Visual factors in the design of military aircraft. *J. Aviation Med.*, 1946, v. 17, April, pp. 115-122.

In a study by the Air Technical Service Command, the importance of diurnal visual acuity, depth perception, visual fields, and night vision are recognized. Aircraft should be designed so as to allow these human factors to be at their maximum efficiency. The importance of mechanical design, and of improved optical materials and their use, is stressed. (5 figures, 2 tables, references.) Bennett W. Muir.

Rochon-Duvignon A. and Aubaret. Jacques Daviel: His life and the discovery of cataract extraction. *Ann. d'Ocul.*, 1946, v. 179, Jan., pp. 1-23.

Monday, April 8, 1745, was an epoch-making day in ophthalmology. A small man of about fifty had successfully performed the first complete cataract extraction in history. This issue of the *Annales* commemorates the two hundredth anniversary of this great event and is largely dedicated to the memory of the father of French ophthalmology.

Daviel conceived the need of a complete cataract extraction about 1741, when he unsuccessfully performed a bilateral reclinatio for cataract on the eyes of the hermit of Aguires. In the second eye fragments of the lens cortex fell into the anterior chamber and this occurrence prevented his pushing the lens backward and downward into the vitreous. He apparently knew that Petit had previously removed dislocated lens matter from the anterior chamber through an incision at the lower limbus.

His first three operations, reported in 1743, were performed with a bistoury-like knife, a needle, and a probe-like instrument on a handle. Four years of effort and experiment resulted in his improved technique. An incision was made in the lower part of the limbus

with a straight keratome-like knife and enlarged with a curved scissors. The capsule was then opened with a cutting needle, the precursor of the modern cystotome. Through a round pupil the lens was expressed into the anterior chamber from which it was removed with a spoon which still bears his name.

In the following 11 years Daviel reported having performed 354 cataract extractions of which 305 were successful. Among his royal patients were the Royal Princess Palatine and King Ferdinand VII of Spain. Louis XV of France, interested, ordered him to operate on the eyes of a dog, after which he made him oculist to the King.

Daviel was born in Normandy between 1693 and 1696. After completing his medical studies at Hotel Dieu in Paris, he began practicing in Marseilles. When an epidemic of plague had become catastrophic in the Toulon area Daviel volunteered for medical service there, and was cited for his work, courage, and devotion to duty. Upon returning to Marseilles, an attempt to rescind his hospital appointment was made by the city officials for medico-political reasons. At about that time he took up ophthalmology. In 1744 he moved to Paris where he practiced until shortly before his death. In 1762 Daviel developed laryngeal paralysis. He went to Geneva because of his health and there he died September 30, 1762, where his body still remains.

Charles A. Bahn.

Smith, V. M. **Rehabilitation of the partially seeing.** *Sight-Saving Review*, 1946, v. 16, Spring, pp. 31-35.

Evaluation of eyesight should be based on the central visual acuity of each eye, binocular vision, muscle action, peripheral vision, and color

vision. Illumination should be adequate, and free from glare. Work should be arranged to prevent ocular fatigue and should be selected with consideration of the patient's disability. Braille should not be taught until it is necessary. The ophthalmologist should recommend in his report what the patient may do. I. E. Gaynon.

19

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Katzin, H. M. **Photography of the external eye.** *Arch. of Ophth.*, 1946, v. 35, May, pp. 514-518.

Photographic reproduction of the eye has become an indispensable part of teaching, research, and medical records. The mechanical problems involved are different from those found in general photography or photomicrography because the eye is neither gross nor microscopic in size. The problems are really those of low power photomicrography. Further, because of the problem of blinking, particularly in photophobic eyes, the light source should be synchronized with the shutter of the camera, and the time of exposure must be minimal. Many types of cameras have been used for this purpose.

A discussion of the film, lenses, depth of focus, focusing, and lighting is given and the camera setup used by the author is described.

R. W. Danielson.

Stone, L. S. **Return of vision in transplanted adult salamander eyes after seven days of refrigeration.** *Arch. of Ophth.*, 1946, v. 35, Feb., pp. 135-144. The adult eye of the salamander may be transplanted with a return of vision. A new lens is regenerated from the

dorsal pupillary margin of the iris and a new retina from the undegenerated ciliary margin of the old retina. Seventy enucleated eyes of the adult salamander, *Triturus viridescens*, were refrigerated at a temperature of from 0 to 8°C. in sterile Ringer solution for periods ranging from two to fourteen days and were then transplanted into freshly denuded orbits of new hosts. After two days of refrigeration at 8°C. some of the eyes eventually became normally functioning organs. Refrigeration for longer than two days required a lower temperature (4 to 6°C.) to insure survival of the graft and successful transplantation. Eyes isolated as long as seven days at this temperature were successfully grafted, and return of vision was demonstrated a little over three months after they were transplanted. These eyes remained functional and were normal in appearance one year after they were grafted.

John C. Long.

Warkany, J. and Schraffenberger, E.
Congenital malformations induced in

rats by maternal vitamin A deficiency. Arch. of Ophth., 1946, v. 35, Feb., pp. 150-169.

When female rats were raised and bred on a dietary regimen which leads to extreme vitamin A deficiency during pregnancy, congenitally deformed offspring were obtained. There were various defects of the skeleton and some defects of the soft tissues. Sections of the eyes showed a fibrous retrolenticular membrane in place of the vitreous in every specimen. In addition there were frequently colobomas, eversion and abnormal structure of the retina, rudimentary development of the iris and of the ocular chambers, defects of the cornea and of the conjunctiva and lack of fusion of the lids. These congenital abnormalities consisted partly of structures arrested in early ontogenetic stages and partly of formations that do not correspond to normal embryonic conditions. When the maternal diet was supplemented with vitamin A during pregnancy, the eyes of the young were normal. John C. Long.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month

DEATHS

Dr. Carl Bishop, Plainville, New Jersey, died July 27, 1946, aged 46 years.

Dr. Joseph Marie Louis Bruno, Brooklyn, New York, died July 14, 1946, aged 52 years.

Dr. Phillips Eagleton, Newark, New Jersey, died September 11, 1946, aged 80 years.

Dr. Charles Willard Geiger, Kankakee, Illinois, died July 19, 1946, aged 75 years.

Dr. Gaylord Crawford Hall, Louisville, Kentucky, died June 16, 1946, aged 66 years.

Dr. Thomas D'Arcy McGregor, Buffalo, New York, died July 14, 1946, aged 52 years.

Dr. Joseph Louis Nocentini, Philadelphia, Pennsylvania, missing in action January 12, 1944, determined dead June 13, 1945, aged 34 years.

Dr. Robert Von der Heydt, Chicago, Illinois, died September 18, 1946, aged 71 years.

MISCELLANEOUS

The first international fellowship to be granted by The Eye-Bank for Sight Restoration, Inc., 210 East 64th Street, New York 21, has been announced by Mrs. Henry Breckinridge, executive director.

The candidate, chosen because of his outstanding qualifications, to be awarded this fellowship is an ophthalmologist of the Hebrew University in Palestine. He will receive post-graduate training in ophthalmology and research work in problems relating to the cornea at the Wilmer Institute, Johns Hopkins University, Baltimore, Maryland.

Dr. Grant Balding, 117 East Colorado Street, Pasadena, California; Dr. Paul L. Cusick, 1108 Stroh Building, Detroit, Michigan; Dr. Frederick C. Cordes, 384 Post Street, Dr. Max Fine, 350 Post Street, San Francisco, California, and Dr. L. Connor Moss, 1710 Rhode Island Avenue, N.W., Washington, D.C., have been named consultants in ophthalmology to the Secretary of War.

Major Gen. Norman T. Kirk, the Surgeon General of the Army, under whose direction the Armed Services medical consultant program was initiated during the war, said that the appointment of civilian consultants will augment the Army staff of doctors caring for soldier patients, and will evaluate, promote, and improve, wherever possible, the quality of medical care given American soldiers.

The state committee on ophthalmology has recommended to the house of delegates of the Minnesota State Medical Association that an eye bank be established. This eye bank will be similar to the Eye Bank for Sight Restoration, Inc., in New York, and the one in Cook County Hospital, Chicago.

Each Thursday during October, Dr. Byron Smith gave a lecture on "Ophthalmic plastic surgery" at the Manhattan Eye, Ear, and Throat Hospital, 210 East 64th Street, New York 21.

La Sociedad Cubana de Oftalmologia is looking forward to the third Pan American Congress to be held in Havana in February, 1948, under the auspices of the Cuban government. A movement for the foundation of a League Against Blindness is headed by the wife of the president of the Republic. Work has already begun on a hospital for the treatment of eye diseases among the poor. The foundation stone of the building has been laid, and it is hoped the building will be finished and functioning perfectly by the time the Congress convenes in Havana.

The Alabama Sight Conservation Association has recently donated \$10,000 to the Department of Ophthalmology of the Medical College of Alabama, to provide equipment for the University Eye Clinic. The Alabama Sight Conservation Association was originated and is sponsored by the Lions Clubs of Alabama.

SOCIETIES

Among the special guests taking part in the program of the American Academy of Ophthalmology and Otolaryngology at the Palmer House, Chicago, October 13th to 18th were: Dr. James B. Brown, St. Louis; Raymond Carhart, Ph.D., Evanston, Illinois; Mr. Howard Carter, Chicago; Helen Goodell, New York; Dr. Fremont C. Hall, Chester, Pennsylvania; Dr. Robison D. Harley, Atlantic City, New Jersey; Dr. Merrill B. Hayes, Chester, Pennsylvania; Dr. Horton C. Hinshaw, Rochester, Minnesota; Thomas H. Holmes, New York; Dr. James T. Mills, Dallas, Texas; Prof. W. J. B. Riddell, Scotland; Dr. Benjamin Rones, Washington, D.C.; Dr. L. von Sallmann, New York; Dr. C. L. Schepens, Brussels, Belgium;

Lieut. Col. Emory L. Shiflett, Cleveland; Dr. Frederick W. Stocker, Durham, North Carolina; Harold Westlake, Ph.D., Chicago; Helenor Campbell Wilder, Washington, D.C.; Dr. Stewart G. Wolf, Jr., New York; and Dr. Harold G. Wolff, New York.

The 1946 session, under the presidency of Dr. Gordon B. New, Rochester, Minnesota, had for its guest of honor, Dr. George M. Coates, Philadelphia. Dr. Curtis F. Burnam, Dr. Samuel J. Crowe, and Dr. Charles E. Iliff, Jr., all of Baltimore, presented a symposium on radiation therapy. Dr. Crowe's presentation was the Wherry Memorial Lecture.

The American Orthoptics Council had a

joint session with the American Association of Orthoptic Technicians.

PERSONALS

The following citation accompanied the award of the Legion of Merit to Dr. James N. Greear, Jr., 3532 Edmund Street, N.W., Washington, D.C. As a lieutenant colonel, Dr. Greear "rendered distinguished service as Chief of the Eye, Ear, Nose, and Throat Service, Valley Forge General Hospital, Phoenixville, Pennsylvania, from October, 1943, to February, 1945. Through his outstanding background, tact, and professional ability, Colonel Greear contributed greatly to facilitating the high standard of care rendered blind patients. . . ."

SIGNIFICANCE OF A MONONUCLEAR-CELL REACTION

Mononuclear cells, and the lymphocyte in particular, were consistently the predominant cells in exudates, smears, and scrapings from epidemic keratoconjunctivitis and acute follicular conjunctivitis, Béal; in the exudates, in fact, almost 100 percent of the cells (fig. 2) were mononuclear. Only in a few cases in which there was secondary infection with staphylococci were there any appreciable

reactions. This was consistent with the generally recognized fact that a lymphocytic reaction is the usual cell reaction to the typical viruses. In fact, the only pyogenic viruses known to involve the conjunctiva—namely, the viruses of trachoma (fig. 3), inclusion conjunctivitis, and lymphogranuloma venereum—cannot be classed as typical viruses and are soon to be placed in a separate category.⁸

In mononuclear-cell exudates, as well as in certain polymorphonuclear-cell exu-

Figs. 2 and 3 (Thygeson). Fig. 2, Mononuclear cell exudate in acute follicular conjunctivitis, Béal. Giemsa stain. ($\times 350$). Fig. 3, Polymorphonuclear leukocytes in exudate from acute trachoma. Giemsa stain. ($\times 350$).

numbers of polymorphonuclear cells. The preponderant cell was the small lymphocyte, but there were variable numbers of large mononuclear cells, most of them monocytes. Some difficulty was encountered in differentiating monocytes with round nuclei from large lymphocytes, but differentiation did not seem to be important. No reason could be advanced to indicate why the large mononuclear leukocytes were more prominent in one case than in another of the same disease.

It is of interest that the only case of acute herpetic conjunctivitis and three cases of conjunctivitis secondary to molluscum-contagiosum nodules of the lid margins showed pure mononuclear cell

exudates in which a significant proportion of the cells were monocytes, many shadow forms of the monocytes occurred. These shadow forms consisted of degenerated nuclei in which the mesh of the chromatin network had become widened to form many bizarre shapes and forms. While there was a certain variation in their number in the various conjunctivitides, no diagnostic significance could be ascribed to them.

SIGNIFICANCE OF A PLASMA-CELL REACTION

In spite of the well-known occurrence of plasma cells in the subepithelial infiltrate in many types of conjunctivitis,

plasma cells in the exudates and epithelial scrapings in this series were extraordinarily rare. In fact, with only a few exceptions, plasma cells were seen only in the scrapings and exudates from trachoma. According to Wilson,⁹ the plasma cell is the most important cell in the subepithelial infiltrate in trachoma, where it occurs in large numbers, and it is of interest that plasmomas not infrequently occur in chronic trachoma of high in-

appear in epithelial scrapings and exudate smears.

SIGNIFICANCE OF EPITHELIAL CHANGES

In vitamin-A deficiency of advanced degree, there is a tendency of the conjunctival and corneal epithelium to become keratinized. This is a characteristic of the conditions known variously as xerosis, xerophthalmia, and keratomalacia. In these conditions, the keratinization is grossly visible, and microscopic study unnecessary. Mild degrees of vitamin-A deficiency sometimes produce the condition known as prexerosis, in which the epithelial changes are mild and localized. Bitôt's spots, which are small, triangular areas of keratinization located selectively at the temporal limbus, are of some value in the diagnosis of vitamin-A deficiency and, in their early stages, can best be demonstrated microscopically. Epithelial scrapings from the temporal limbus area show keratinized epithelium, usually covered with xerosis bacilli (fig. 4). In Giemsa stains, the cells appear reddish, and the nuclei are absent or degenerated. The normal conjunctival epithelium of this area never shows keratinization or surface bacterial proliferation.

Fig. 4 (Thygeson). Epithelial scrapings from the bulbar conjunctiva of a patient with vitamin-A deficiency. Giemsa stain. Drawn from a magnification of 1,350.

tensity. The plasma cells in trachoma exudates in this series were never very numerous but were easily recognized and distinctive. It is believed that their presence has some diagnostic importance.

It is not certainly known whether the plasma cell has the ability to pass through the epithelial barrier of the conjunctiva or is seen merely as the result of the rupturing of trachoma follicles. As will be noted later, the gelatinous necrotic trachoma follicles rupture easily, even spontaneously, and it would therefore seem logical to expect plasma cells contained in the periphery of the follicles to

The value of this test has been questioned,¹⁰ but it is believed by the writer to have considerable value, although limited in this country by the relative infrequency of vitamin-A deficiency. In this series of 2,000 cases, for example, only eight instances of keratinization due to vitamin deficiency occurred. It is interesting that one of these was a pellagra due to chronic alcoholism. In the only three of the eight cases which could be followed for any length of time, vitamin-A therapy caused a disappearance of Bitôt's spots and a return of the conjunctival epithelium to normal.

Keratinization of the conjunctival

epithelium may occur, however, without relation to vitamin-A deficiency. It may occur as a result of exposure in old cases of ectropion or as a result of extreme cicatrization, as in old trachoma or ocular pemphigus. These conditions, however, present no diagnostic difficulty and are in no danger of being confused with suspected vitamin-A deficiency.

It should be remembered that the epithelium of the lid margin is normally keratinized and that occasionally keratinized cells from this source may appear in conjunctival smears. This is extremely rare, however, and caused no confusion in this series.

Keratinization without vitamin-A deficiency may also occur in the syndrome of keratoconjunctivitis sicca. In this disease, there is a deficiency of tears which is compensated for by the production of excessive amounts of mucus. While the conjunctival epithelium never becomes fully keratinized as in vitamin-A deficiency, the cells from an advanced case characteristically show keratin granules in the cytoplasm and degenerative changes in the nuclei. These changes (fig. 5) are so characteristic as to be of diagnostic significance. An extraordinary increase in the number of goblet cells in scrapings and an excessive amount of mucus complete a characteristic microscopic picture.

According to various authors, notably Feldmann¹¹ and Taborisky,¹² there are epithelial changes in trachoma other than the cytoplasmic inclusions which have diagnostic significance. Feldmann states that an early diagnosis of trachoma can be made from a study of scrapings from the tarsal conjunctiva. She states that in scrapings from the normal conjunctiva the epithelial cells come off in sheets, the nuclei are oval and of uniform size, and the staining of the nuclei is uniform and saturated. In trachoma, she

notes that the polymorphism of the epithelial cells is striking, that they tend to appear in scrapings as isolated cells rather than in sheets, and that their nuclei are round, variable in size, and larger than usual, staining irregularly and less intensely. She indicates that these observations were consistent in 356 cases of trachoma.

According to Taborisky, a cytodiagnosis of trachoma can be made as early as

Fig. 5 (Thygeson). Mucus and partially keratinized epithelial cells in conjunctival scrapings from keratoconjunctivitis sicca. Giemsa stain. Drawn from a magnification of 1,350.

the fifth day of the disease. The normal cylindrical cells of the conjunctiva become flattened, and the nuclei show characteristic changes consisting of thickening and poor staining of the chromatin network with irregularities in the nuclear membranes. He believes that these changes occur in no other type of conjunctivitis.

Observations on the 125 cases of trachoma in this series, however, failed to show epithelial changes which could be considered specific. It was true that the epithelial cells in trachoma tended to show polymorphism and irregular stain-

ing, but these same morphologic variations were also seen in cases of non-trachomatous conjunctivitis, particularly long-standing conjunctivitis. As will be stressed later, I consider the cytologic findings in expressed follicular material to be much more characteristic of trachoma than any epithelial changes.

Fig. 6 (Thygeson). Follicular expression from trachoma, showing Leber cells, degenerated lymphoblasts, and cell debris. Giemsa stain. Drawn from a magnification of 1,350.

CYTOLOGY OF EXPRESSED FOLLICULAR MATERIAL

An extensive study was made of follicular expressions from trachoma and from nontrachomatous follicular conjunctivitis of various types. No difficulty was encountered in obtaining satisfactory preparations from trachoma, since the follicles were soft, gelatinous, and easily expressed. In contrast, all the nontrachomatous follicular conjunctivitis had hard, nonexpressible follicles from which material could be obtained only as a result of vigorous manipulation with ring forceps.

There was a very decided and diagnostic difference between the cytologic pic-

ture (fig. 6.) of the trachoma material and of the material from the other diseases. In trachoma, the predominant cell was the germinal-center cell, believed to be a lymphoblast. In lesser numbers were lymphocytes, plasma cells, occasional monocytes, and macrophages. The lymphoblasts had a very characteristic appearance. They showed many degenerative changes, varying in intensity from pallor of the nuclei to loss of cytoplasm. Scattered throughout the slide were many clumps of cell debris, mostly cytoplasmic. The appearance of the macrophages was also distinctive. They were the large macrophages (Leber cells), sometimes several times the size of epithelial cells, and contained in their cytoplasm masses of phagocytosed cell debris, largely nuclear in origin. In slides from typical active trachoma these large macrophages or Leber cells were quite numerous, as many as 25 occurring in a single slide. Ordinarily, however, their number varied between 5 and 20 per slide. Altogether a very characteristic cytologic picture was observed in every case of active trachoma.

A quite different cytologic picture was seen in nontrachomatous follicular material. Here the small mononuclear cells, mostly lymphocytes, were predominant, and there were none of the degenerative changes so characteristic of trachoma. The small number of lymphoblasts present showed normal staining and never any cytoplasmic fragmentation. There was almost complete absence of the cell debris so characteristic of trachoma. Macrophages were occasionally seen, however, but their number was never comparable to the number seen in trachoma, and there were no typical Leber cells.

The explanation for the differences in the cytologic pictures of the two types of

follicular disease probably lies in the necrotizing action of trachoma toxins. It is, of course, the cell necrosis in trachoma which results in the cicatrization so char-

minal-center cells in trachoma and for their paucity in the nontrachomatous diseases. This is probably due to the fact that the trachoma follicles are necrotic

acteristic of the disease and which is completely absent from all the other follicular diseases. It is also interesting to speculate on the reason for the predominance of the large mononuclear, ger-

and express easily in such a way that only the germinal-center material is lost, whereas, in follicular conjunctivitis, the whole follicle has to be extirpated in order to get a satisfactory smear. In a

whole follicle, the small mononuclear cells are, of course, more numerous than the germinal-center cells.

DISCUSSION

As was expected, the polymorphonuclear-cell reaction was the most common cytologic feature of exudates from conjunctivitis. In most infections, the demonstration of this reaction pointed to a pyogenic bacterium as the etiologic agent, but there were some notable exceptions. For example, the three atypical viruses of ocular importance, all members of the psittacosis - lymphogranuloma - venereum group of viruses, were all pyogenic. The typical viruses, on the other hand, as exemplified by herpes-simplex virus, induced an almost purely mononuclear-cell reaction. On this basis, the demonstration of polymorphonuclear cells in the exudates of the conjunctivitis from erythema multiforme and psoriasis arthropathica, diseases of unknown etiology, suggests that typical viruses, at least, are not concerned in their etiologies.

The only fungus concerned in conjunctivitis in this series—namely, *Streptothrix foersteri*,¹³ the causative organism of streptothrix concretions of the canaliculus—was also definitely pyogenic, inducing a marked polymorphonuclear-cell reaction in the exudates from the secondary conjunctivitis. On the other hand, the mild conjunctivitis secondary to pure seborrheic blepharitis,¹⁴ and believed to be caused by *Pityrosporum ovale*, was extraordinarily low in leukocytes. Over half the cases of phlyctenular conjunctivitis in the series were characterized by a polymorphonuclear exudate, but it is noteworthy that there was an almost absolute correlation between this cell reaction and the occurrence of secondary staphylococcic infection. In the few uncomplicated cases, it was difficult to demonstrate any leukocytes whatever in the scanty exudate, if indeed there was any

exudate at all. When leukocytes were present, they were almost equally divided between polymorphonuclear and mononuclear cells.

As can be seen, therefore, the diagnostic significance of a polymorphonuclear-cell exudate was limited, but there were certain cases in which its demonstration was of decided value. For example, differentiation between the acute follicular conjunctivitis due to inclusion-conjunctivitis virus and Béal's conjunctivitis¹⁵ of still unknown etiology, which at onset are often indistinguishable, could readily be made from an examination of the exudate, since inclusion conjunctivitis has a polymorphonuclear-cell reaction and Béal's conjunctivitis a mononuclear-cell reaction.

The demonstration of a mononuclear-cell reaction was found to have considerably more diagnostic value. As was expected, the typical viruses such as herpes-simplex virus, the virus of epidemic keratoconjunctivitis, and the virus of molluscum contagiosum, induced a lymphocytic reaction which was of considerable value in diagnosis when correlated with clinical and bacteriologic findings. The demonstration of a pure mononuclear-cell reaction in Béal's conjunctivitis suggests strongly that the agent of this infection will eventually be shown to be one of the typical viruses. It must be remembered, however, that there is at least one bacterium—namely, *L. monocytogenes*—which has the ability to induce a mononuclear-cell reaction. To the best of my knowledge this organism has never been found in human conjunctivitis, however, although an experimental ocular infection in rabbits has been studied by Julianelle.¹⁶

As was expected, the eosinophil was the cell having the greatest diagnostic value. It is well known that the eosinophil in small numbers may be present in tissue infiltrations without an allergic

basis, but, except for its occurrence in ocular pemphigus, a conjunctival eosinophilia proved to be an almost certain indicator of conjunctival allergy. Conjunctival eosinophilia has been reported in ultraviolet light conjunctivitis¹⁷ and in self-induced conjunctivitis due to ipecac,¹⁸ but the few cases of arc burns in this series showed no leukocytic reaction whatever. There were no cases of self-induced conjunctivitis, and drug conjunctivitis was accompanied by an eosinophilia only when an actual sensitivity had developed. For example, eosinophils were never demonstrable in the silver-nitrate conjunctivitis produced in newborn babies by the Cr  d   procedure. The fact that ocular pemphigus always showed a mild conjunctival eosinophilia was of some interest but in no way confusing, since the clinical picture of ocular pemphigus was always distinctive enough to eliminate the possibility of typical allergy. Of more significance was the fact that old cicatricial trachoma never showed conjunctival eosinophilia, whereas old cicatricial ocular pemphigus always did. Although differentiation between these two diseases can usually be made on clinical findings alone, a few cases occurred in this series in which the cytologic findings had distinct diagnostic value.

That a conjunctival basophilia usually paralleled a conjunctival eosinophilia was an unexpected finding and one which is believed to have definite diagnostic possibilities. Although isolated basophils were found in many other types of conjunctivitis, they were not found in any considerable numbers except in typical conjunctival allergy. The basophil is a cell more easily recognized than is the eosinophil, particularly by persons with any degree of color-blindness, and can always be recognized with the low-power objective of the microscope.

In this series, no satisfactory study of the granulomatous conjunctivitis was

possible. Two cases of tuberculosis with hypertrophic nodules showed no exudates at all; whereas, one with a single conjunctival ulcer showed polymorphonuclear cells as the most common cells in scrapings from the base of the ulcer. As is well known, this leukocyte is seen in tuberculous lesions only when necrosis has taken place. There were six cases of conjunctivitis due to the *Leptothrix* (Verhoeff¹⁹), but in only two of these was there sufficient exudate for cytologic examination. In these two cases, polymorphonuclear and mononuclear cells occurred in about equal numbers. There were no cases of tularemia or syphilis.

Cytologic studies of expressed follicular contents from trachoma and from various other etiologic types of follicular conjunctivitis offered considerable diagnostic interest. The phenomenon of necrosis so characteristic of the trachoma follicle was completely absent in the follicles of the other conditions. No diagnostic differences among these other non-trachomatous follicles could be made out, but the differences between them and the trachoma follicle were striking. The significance of this observation is somewhat limited by the fact that the contents of the follicle must be mechanically expressed, but it was found to have definite value in certain atypical cases in which clinical differentiation was not possible. It is believed also that these cytologic changes may be useful in differentiating trachoma follicles from nontrachoma follicles in the same individual in whom trachoma may have supervened on a conjunctiva already showing follicular hypertrophy.

In my opinion, cytologic studies should be a routine part of the examination of conjunctival disease and should be reported simultaneously with the bacteriologic findings.

SUMMARY AND CONCLUSIONS

1. In a microscopic study of exudate

smears and conjunctival scrapings from 2,000 cases of conjunctivitis of diverse etiology, variations in leukocytic reactions and epithelial changes were found to be sufficiently marked to have diagnostic value.

2. Polymorphonuclear-cell exudates were characteristic of bacterial infections in general, but there were a few exceptions. Diplobacillary conjunctivitis was characterized by a fibrinous exudate without leukocytes unless there was secondary infection with staphylococci. Chronic N. catarrhalis conjunctivitis also showed minimal or no leukocytic reaction.

3. Conjunctivitis produced by the typical viruses always showed a characteristic mononuclear-cell exudate with few, if any, polymorphonuclear cells. In contrast, the three viruses of the psittacosis-lymphogranuloma - venereum group of viruses—namely, trachoma, inclusion conjunctivitis, and lymphogranuloma venereum viruses—always showed a polymorphonuclear-cell exudate.

4. Epithelial changes consisting of various degrees of keratinization were of value in the diagnosis of early vitamin-A deficiency. Mild keratinization of the epithelium combined with an increase in goblet cells and mucus was characteristic of keratoconjunctivitis sicca.

5. A predominance of eosinophils in

the exudate was characteristic of vernal catarrh and of typical conjunctival allergies such as hay-fever conjunctivitis. Bacterial allergy; as exemplified by phlyctenular conjunctivitis, showed no eosinophils in the exudate. A conjunctival basophilia was also found in the typical allergies but was neither so constant nor so specific as the eosinophilia. The occurrence of free eosinophilic and basophilic granules released from disintegrating cells was found to have some diagnostic value.

6. The cytology of expressed-follicle contents showed striking differences between the cells of trachoma and those of other follicular conjunctivitis. These differences appeared to be related to the fact that cell necrosis is a striking feature of trachoma but not of the other diseases.

7. The cytologic changes found in this study were in only a few exceptional instances pathognomonic of the etiologic type of conjunctivitis concerned, but when correlated with clinical and bacteriologic findings they were often of distinct diagnostic importance.

8. It is recommended that a statement on cytology be a part of every laboratory report on conjunctival scrapings or exudates.

DISCUSSION

DR. PARKER HEATH (Detroit, Michigan): Dr. James H. Allen asks: "Can a distinction be made between acute conjunctivitis, type Béal, and epidemic keratoconjunctivitis by cytologic study?"

DR. PHILLIPS THYGESON (San Jose, California): At the present moment, I don't think any distinction can be made between the cytologic findings in these two diseases. We at one time thought that there were specific inclusion bodies associated with epidemic conjunctivitis; that is, bluish, amorphous bodies in the cytoplasm of conjunctival and corneal epithelial cells which had some diagnostic significance, but we have since found these same bodies in other diseases, and we think they are probably nonspecific.

DR. HEATH: The second question Dr. Allen wishes to ask is: "Do you consider macrophages (Leber's cells) pathognomonic of trachoma?"

DR. THYGESON: The Leber's cell is nothing but a large macrophage. They were in trachoma, certainly more numerous than in any other types of conjunctivitis studied, but they were also found in other infections. It seems to me that the presence of numerous Leber's cells in association with signs of cell necrosis and a predominance of lymphoblasts does indeed make a pathognomonic picture. I believe macrophages in other types of conjunctivitis tend to be definitely smaller than the Leber cell which is an extraordinarily large macrophage.

I am sure that the cells stem from the

same origin, but there is an extraordinary size difference between macrophages from trachoma and those from other types of conjunctivitis.

DR. HEATH: Dr. Allen's third question is: "Will you discuss the importance of proper selection of the site for removal of material for cytologic study?"

DR. THYGESON: It is a good rule to take cytologic material from the point of maximum disease intensity. Where exudate smears are taken, this is not of much significance, since most exudate accumulates in the inner canthus. Scrapings, however, are best taken from the site of maximum disease intensity.

When one is looking for suspected vitamin-A deficiency, it is important to recognize that the temporal limbus is the site most commonly affected in early deficiency. We would then take our scrapings from the outer temporal limbus area. This is the site where a Bitôt's spot is most commonly seen.

DR. HEATH: Dr. Donald J. Lyle asks the fourth question: "What are the best stains to use routinely in the laboratory investigation?"

DR. THYGESON: I have used about a half-dozen different cytologic stains, and I definitely prefer the Giemsa stain. We fix our material in absolute methyl alcohol and then stain in dilute Giemsa solution (1 drop to 2 c.c. of neutral distilled water) for about an hour. We then pass the slide through two changes of 95-percent alcohol to remove the stain débris. This makes a

very satisfactory cytologic stain. Then, there is the Wright's stain, which is satisfactory and more rapid. I am sure there are two or three other stains which would work equally well, but I, personally, prefer the Giemsa.

DR. HEATH: Dr. V. C. Rombo asks: "Please discuss the differentiation between inclusion blennorrhea and trachoma."

DR. THYGESON: I think it is perfectly possible to make a cytologic differentiation between these two diseases, especially in the adult. Both diseases have identical inclusion bodies; both diseases are characterized by a polymorphonuclear-cell exudate. It is the follicle cytology which makes the differentiation possible. In inclusion conjunctivitis in the adult, the follicles show none of the degenerative changes characteristic of trachoma, and one gets the cytologic picture of the nontrachomatous follicle in contrast to the numerous cytologic changes so characteristic of trachoma.

I recognize that clinical differentiation is possible in most cases, but there are certainly occasional confusing cases in which cytologic study may be of value.

DR. HEATH: This question is from Dr. K. W. Ascher: "Did you observe, in cases of vitamin-A deficiency, syncytiumlike membranes of keratomized epithelial cells?"

DR. THYGESON: I may have seen those but I did not recognize them as particularly characteristic. I am sorry; I really can't answer that question.

DR. EDWARD C. ELLETT (Memphis Tennessee): In speaking of the reaction to atropine, Dr. Thygeson made the distinction that the reaction to atropine was an allergic reaction and that to eserine was a toxic reaction. I should like to ask if he made any sensitivity tests for these two drugs in these conditions.

DR. THYGESON (closing): First of all, I noted that there was a very marked clinical difference between the conjunctivitis produced by these two drugs. The atropine reaction was typically a contact conjunctivitis and dermatitis, with widespread dermatitis of the eyelids; whereas, I never saw skin reactions in eserine catarrh. I recognize that these may well occur, but I have not seen them, personally. Secondly, I noted that the conjunctival reaction in atropine conjunctivitis was a papillary hypertrophy; whereas, in eserine conjunctivitis it was a follicular hypertrophy.

I made a number of tests, both by patch and by intradermal methods, and I was consistently able to obtain a positive patch test to atropine. Some were low grade, and others rather violent. However, I never succeeded in obtaining a patch test to eserine. I did not make serologic studies.

CONTRIBUTIONS TO THE SURGERY OF CONGENITAL CATARACT*

I. MODIFICATION OF DISCISSION IN THE PRESCHOOL AGE GROUP

WILLIAM F. MONCREIFF, M.D.

Chicago

The present essay will attempt an analysis and evaluation of some important problems encountered in the surgery of the congenitally cataractous lens in the young child. It will present certain modifications of technique, devised and developed by me within the past two years, which are applicable to the preschool child, between the ages of one and six years, together with a report of three cases in which this method was employed.

Certain criteria may be stated to which any operation for congenital cataract in this early period of life, if it is to be adequately safe and efficient, should conform:

1. A single operative procedure should provide for rapid and complete absorption of the lens cortex and nucleus within four to eight weeks, without any but the most remote danger of severe reaction or increased tension. Thus, the need for a second operative procedure, or discission of a thin membrane, would be at least as infrequent as following extracapsular extraction of adult cataract, and correcting lenses could be prescribed within one to two months after operation, as in the case of the adult patient.

2. The incision in the limbus should be minimal, scarcely more than a puncture, so as to avoid prolapse or incarceration of the iris or other structures.

3. The operation should be limited to the lens, and should not involve the iris,

the vitreous, or even the posterior capsule of the lens.

The author's procedure, omitting ordinary routine details of preoperative preparation and anesthesia, is briefly as follows. First of all, the most complete mydriasis (fig. 1) possible to attain by any or all means must be secured. There

Fig. 1 (Moncreiff). Preoperative dilatation of the pupil.

are several reasons for this. They are:

The wider the pupil, the greater will be the expanse of the pupillary portion of the anterior chamber; thus, the more readily can lens substance enter the anterior chamber and remain there. Most important is the greater access thereby gained to the outlying portions of the anterior part of the lens approaching the equatorial region. Finally, there is the fact that the wider the pupil at the time of operation, the less the difficulty of maintaining a wide pupil after operation.

The knife-needle enters through the limbus at the temporal end of the hori-

*From the Departments of Ophthalmology of Cook County Hospital and of the College of Medicine, University of Illinois. Read before the Chicago Ophthalmological Society, March 18, 1946.

Fig. 2 (Moncreiff). Primary incision into the lens.

zontal meridian of the cornea, makes a vertical incision through the anterior capsule and into the cortex (fig. 2), and then multiple incisions in all directions through the lens capsule and anterior cortex (fig. 3), down to the nucleus, across the full expanse of the widely dilated pupil, until the anterior capsule and anterior cortex are literally reduced to shreds and small particles (fig. 4). When the nucleus appears and separates from the cortex, it is cut into several fragments (figs. 4 and 5), and a few light strokes are made into the posterior cortex, taking care not to puncture the posterior capsule, or to lose aqueous. With a properly made instrument, such as my model of the

Fig. 3 (Moncreiff). Consecutive incisions into the lens.

Ziegler knife-needle, the operation can be carried to this point with little or no aqueous loss. The knife-needle is then withdrawn, permitting the escape of some aqueous. The tip (23 gauge) of the anterior-chamber irrigator (fig. 6) is then introduced through the knife-needle puncture, and fluid injected in the direction of the posterior capsule and toward the center of the pupil (fig. 5). This has the effect of removing cortical material from the remnants of the capsular sac and displacing it into the anterior chamber.

Fig. 4 (Moncreiff). Division of the lens nucleus.

Should it happen through accident or faulty technique that too much aqueous escapes before the multiple incisions of the lens are completed, the irrigator should be used to restore the anterior chamber, and another knife-needle of slightly larger size introduced through the same puncture to complete the division of the lens structure.

The essential feature of postoperative care is to maintain the wide dilatation of the pupil, which is much more readily done after this type of operation than after the conventional discission. It need scarcely be said that in addition to atropine ointments of whatever dosage can be borne by the individual patient, great reliance is placed, both pre- and postoperatively, on epinephrine-type drugs which

are powerful stimulants of the dilator pupillae, particularly neosynephrin in a 10-percent solution or emulsion.

From May 1, 1944, to May 9, 1945, the operative procedure just described was employed in six eyes of three patients, as follows.

CASE REPORTS

Case 1. J. V., a colored girl, aged 14 months, was first examined on April 20, 1944. Her history told of white pupils being noted at birth. The child had always been poorly developed physically. A physical survey revealed general under-

Fig. 5 (Moncreiff). Introduction of irrigator tip and displacement of lens fragments into anterior chamber.

nourishment and underdevelopment, with congenital heart disease. Body weight was only 18 lbs. The eyes exhibited asymmetrical pendulum nystagmoid movements. Pupillary reaction to light was normal; the irides were dark brown; the dull-white lenses were completely opaque; there was no fundus reflex even through the periphery, with widely dilated pupils.

Operative procedure on both eyes, under general anesthesia, was undertaken on April 26, 1944. In this case, a small, narrow Graefe knife was used for the

primary puncture at the limbus, and the incision of the anterior capsule and cortex of the lens. The knife-needle was then substituted for the remainder of the lens incisions. The irrigator tip was then introduced, and the fragments of lens sub-

Fig. 6 (Moncreiff). Goldstein anterior-chamber irrigator.

stance displaced into the anterior chamber by injecting physiologic saline solution.

The postoperative course was characterized by a minimum of inflammatory reaction; there was only the faintest bulbar injection. During the first week, the anterior chamber of each eye was entirely filled with fragments of lens substance. Wide dilatation of the pupils was maintained without much difficulty. At the end of four weeks, after gradual absorption, the fundus reflex was clear throughout the pupil of each eye, and only a thin transparent membrane spanned the pupillary space, fringed along the pupillary margins with minute remnants of lens substance.

On June 26, 1944, skiascopy at 0.5 meter showed: R.E., +12.00; L.E., +11.00. No adequate record of visual acuity could be made. The lenses prescribed (according to the skiascopic findings) were: R.E., +10.00; L.E., +9.00

Case 2. B. J. A., colored girl, aged 2½ years, when first examined on November 25, 1944, had a history of being a premature infant with a birth weight of 4 lbs., 11 oz. White pupils were noted at birth. A physical survey revealed nothing especially noteworthy in the general condition. The eyes displayed slow pendulum

nystagmoid movements. Pupillary reaction to light was normal; the irides were dark brown; each lens was completely opaque, as in case 1.

Operative procedure on both eyes, under general anesthesia, was undertaken on November 29, 1944. The details of the operative procedure were substantially the same as in case 1, except that no Graefe knife was used, the knife-needle being used entirely for the discission part of the procedure.

The postoperative course was similar to that in case 1, except that at the end of two weeks the right pupil was entirely clear of lens substance, and the left pupil was almost clear.

This patient was discharged from the hospital two weeks after operation. Since then, coöperation as to return visits has been so poor that no data on the refraction and visual acuity have, as yet, been obtained.

Case 3. R. H., a colored boy, aged five years, was first examined on May 2, 1945. His history included cataractous changes noted in the crystalline lens of each eye at birth by the attending physician. A physical survey revealed his general condition to be normal. The visual acuity of each eye was limited to counting fingers at 3 feet. There was no nystagmus nor nystagmoid movement. In each lens, there was fairly dense central lamellar (or zonular) opacity, apparently about 6 mm. in diameter and of a stellate pattern, lying in the periphery of the fetal nucleus and surrounding layers. There were many fine, white dots of opacity throughout the periphery of each lens. The irides were dark brown. No lesions were found in the portions of the fundi which could be seen through the periphery of the lenses with widely dilated pupils.

Operative procedure on both eyes, under general anesthesia, was undertaken on May 9, 1945; using the same technique

as in case 2. In the right eye, the nucleus was not divided but in the left eye, the nucleus was cut into three fragments.

The postoperative course was characterized, as in the other two cases, by a very slight degree of bulbar injection. The nuclear portion of each lens completely disappeared within a month, by June 4, 1945. The pupillary zone of the right eye was entirely clear of lens material, and the corrected vision of the right eye at this time was 0.8, but not until July 2, 1945, almost two months after operation, was the pupil of the left eye clear.

On June 16, 1945, the refraction of the right eye was: +12D. sph. \ominus +2.50D. cyl. ax. 105° = 0.8 (illit.); and that of the left eye was: +11.75D. sph. \ominus +2.50D. cyl. ax. 90° = 0.8 (illit.). On October 8, 1945, corrected vision was: R.E., 0.8+2 (illit.); L.E., 0.8+3 (illit.).

In addition to these three patients, there were three other patients, operated on during the past two years, who do not fit into this category, as the irrigator technique was not used or needed. The reasons for this were: In one patient the lenses were hypermature; consisting only of capsule containing milky fluid; and, each of the other two patients was under one year of age, at which age the lens structure is so delicate that the entire procedure can easily be accomplished with the knife-needle alone, and without the use of the anterior-chamber irrigator.

REPORTS IN THE LITERATURE

A complete review of the literature is not contemplated in this paper, and reference will be made to only a few publications related to points upon which it is desired to place special emphasis.

Prevention would, of course, be the ideal method of solving the problem of congenital cataract. In so far as the developmental forms are concerned, there are numerous articles in the literature de-

voted to the role of heredity, some complete with extensive and complicated family trees, all of which are of great scientific and academic interest. It may be that in the dim and distant future, by virtue of such studies, the elimination of all hereditary and developmental cataracts will be achieved.

Be that as it may, it would seem that the *surgery* of congenital cataract has been, for the past 25 years, a greatly neglected subject, as indicated by the fact that since Ziegler's¹ publication, in 1921, of his V-shaped or through and through discission of the lens, nothing actually new in principle has been published on this subject, so far as I have been able to discover.

During this 25-year period, although only a relatively few papers dealing with surgical procedures for congenital cataract have appeared, and these devoid of any real solution of the unsolved difficulties, there has been an avalanche of publications concerning adult or so-called senile cataract, most of which lay particular emphasis on surgical procedures. During this period, the modern techniques of intracapsular extraction have been evolved and popularized, and important improvements (in the extracapsular operation), as well as various safety measures for lens extraction in the adult patient, have been devised and rather generally adopted. This discrepancy between the attention accorded the surgery of congenital as compared to that given adult cataracts would not be particularly remarkable were it not for the fact that, previous to these developments of the past 25 years, the results of extracapsular lens extraction in the adult patient, in skilled hands, were already better than the results of any procedure or combination of procedures for congenital cataract. The one possible exception to this assertion is the Ziegler operation to which there are important basic objections, as will be

shown later. Various reports of surgical and visual results in congenital cataract have been made. Usually these reports have been characterized by too high a percentage of surgical complications and failures, entirely aside from the well-known incidence of amblyopia, nystagmus, and various congenital eye defects other than cataract which, of course, ought to be sharply distinguished from the surgical failures.

The most recent contribution of this kind is that of Falls,² whose report of the results in 131 cases at the University of Michigan between 1925 and 1942 will serve as an example. In this series, the number of eyes operated on was 223, and the number of operations 510, plus 14 others which complications necessitated. There were 413 discissions and 64 linear extractions, 60 of which followed discission and were done for the removal of swelling cortical material. In 19 of these eyes, there was increased tension or secondary glaucoma which, in 9 cases, persisted after linear extraction. Falls does not mention in his paper whether or not the Ziegler type of discission was used in any of these cases. However, in a personal communication Dr. Falls said that the Ziegler operation was not done.

Among other supplementary operations employed to relieve complications were: extraction of secondary lens membrane (5), iridocapsulotomy (4), iridectomy for prolapsed iris (4), excision of anterior synechia (2), cyclodialysis (4), Elliot trephine and LaGrange sclerectomy (1 each), and one enucleation. The greatest number of discissions performed on any one eye was six, but the number of eyes on which more than two, or more than three, discissions were performed is not stated. These surgical facts would appear to be more significant in evaluating the efficiency of the surgical methods used than are the visual results reported, since, unfortunately, no selective informa-

tion is given as to which visual defects were chargeable to surgical complications and failures, and which to amblyopia and to congenital defects other than cataract. Postoperatively, 53.5 percent of the 233 eyes attained corrected vision of 6/30 or better; whereas, 16.8 percent were industrially blind, and in 20.6 percent the visual acuity was indeterminate. An attempt is made to draw conclusions as to the relative efficiency of discission alone and discission followed by linear extraction, by citing that only 27.1 percent of the group treated by discission achieved vision of 6/12 or better, compared with 54.9 percent of the group in which discission was followed by linear extraction. However, in comparing acuity for near vision, the advantage, although slight, was with the group treated by discission only, to the extent that 27.7 percent (as compared to 25.4 percent) could read Jaeger 1 to 3.

The final conclusion offered is that "Surgical intervention in early life is hazardous, as shown by the fact that a high percentage of complications and 33 percent of the total failures occurred in the age group under two years." It should be noted, however, that this group was a small minority of the whole series, only 17.5 percent, or 23 patients. The present author doubts the validity of the above conclusion, and considers that, at best, it can apply only to the methods used and to the operators who used them. If any considerable number of the operations on patients under two years of age were done by beginners, then there is the possible factor of a higher proportion of complications in this age group due to insufficiently skilled operators.

In Falls' series, discission of the "lens capsule" was stated to be the safest technique for children under two years of age. This notion about limiting the operation to the capsule (without including the cortex and nucleus) will be

commented upon later. Falls also makes the suggestion that, when the cataractous condition is complete and bilateral, six months of age should be chosen as the time for operation on the first eye, and two years of age for that on the second eye. This suggestion is faulty on both counts.

First, very few, if any, infants will be found, especially those with brown irides, in whom sufficient pupillary dilatation can be obtained at six months to make the operation expedient at so early an age. There are a few at eight months of age, and the proportion increases rapidly until, at one year and older, there are few which present any serious difficulty.

Secondly, if a correcting lens is applied and good vision develops in the first eye, the second eye will have more than a year in which to become amblyopic. A year should be ample time in many cases for the amblyopia to become so fixed as to constitute a troublesome problem in itself. In brief, if both eyes require operation, both should be done at once, barring some definite contraindication.

Let us now examine the prospects of success for the conventional surgical procedures for congenital cataract in terms of the criteria stated in the introductory paragraphs of this article. Under the first heading—a single operative procedure should provide for the rapid and complete absorption of the lens cortex and nucleus, within four to eight weeks—what is the record of ordinary discission? Falls' reference to discission of the "lens capsule" as the safest procedure in the child under two years of age expresses the false conservatism and timidity of many operators of the past, and doubtless some of the present day. If the incision is made with the intention of limiting it to the anterior capsule of the lens, the absorption of the lens substance, in the average case, will be very slow, and one such operation will rarely reduce the lens to a

membrane thin enough to be dealt with definitively and finally by a single subsequent operation. After such an inadequate primary operation, there is usually great difficulty in maintaining a widely dilated pupil, so that the iris itself becomes an obstacle preventing access of aqueous to the lens substance. The consequence is inadequate absorption of the lens substance and, after one or more such procedures, a tough fibrotic mass may result so that no amount of subsequent discission can succeed in obtaining a clear pupil. Uveitis, increased tension, and secondary glaucoma should rarely occur under six years of age with any type of discission, since up to this age the lens is very soft and its nucleus small and not hard. Such young eyes usually react favorably. There are, nevertheless, certain factors which tend to produce these complications and which, at older ages, become very formidable. Faulty technique, in the sense that there is pulling or traction on the zonule and ciliary processes instead of clean cutting into the lens, can cause a marked rise in tension, even within a few hours, and this is usually accompanied or followed by iridocyclitis. There is, of course, no excuse for this faulty technique in any type of discission. The swelling of large masses of lens substance, if located behind the iris and toward the chamber angle, is likely to produce anterior uveitis and increased tension, especially in older children and adolescents.

The author's method attempts to avoid these complications and to insure rapid absorption of lens substance by dividing the lens cortex and nucleus into as many and as small fragments as possible and then by displacing these fragments into the anterior chamber. The lens particles are too large to affect the osmotic equilibrium, so they cannot elevate the tension by that mechanism; and they are too small to cause a rise of tension by mechanical

swelling, particularly since they are away from the chamber angle and in front of the iris. What of the masses of flocculent lens cortex that cannot be divided into small fragments? There is no question that soft lenses vary in their physical properties, and this condition may be encountered in some cases. However, these masses can easily be displaced into the anterior chamber by the use of the irrigator; the only difficulty which they cause is slower absorption.

The criterion set forth under the second heading of the introduction of this article—that the limbal incision should be limited to the puncture of a knife needle—rules out all forms of so-called linear extraction, in which there is an ever present danger of iris prolapse, even in the Barkan³ method of using a keratome incision in the clear cornea. In the case of children under six years of age, and perhaps in some a bit older, there should as a rule be no occasion which requires the extraction of lens substance after discission by the method presented in this paper. However, for discission alone, of whatever type, there is an upper age limit, whether it be 10 or 20 years, and beyond this age limit some method of extracting most of the lens substance will be necessary. The author has in mind a type of procedure for these older patients, with positive safeguards against iris prolapse, which, when sufficiently tried out, will become the basis of a subsequent communication.

The third criterion, stated in the introductory paragraphs, bears on the question of optical iridectomy on the one hand, and the Ziegler operation on the other. Optical iridectomy, such as might be employed for the varieties of congenital cataract with centrally located opacities, requires little comment, since it has been virtually abandoned for two obvious reasons: (1) the optical imperfection of the peripheral and even the paracentral

portions of the lens and cornea; and (2) the importance of the optical and cosmetic functions of the intact pupil, especially in young individuals. On both counts, aphakia with a round pupil is preferable.

In discussing the Ziegler operation, one enters upon what may prove to be the most controversial phase of this entire subject. It is conceded at once that undoubtedly many good, immediate results have been obtained by this method, with a single operation and in record time. (The same can be said, however, for the obsolete couching operation.)

The fundamental question is: What is the future of eyes operated on by the Ziegler method, especially in the later years of the patient's life, when the operating surgeon has long since passed from the scene? Can we really traumatize the vitreous with impunity, especially in the eye of the infant or young child?

This is an important question, and especially so in view of the incomplete state of our knowledge of the pathogenesis of retinal detachment, glaucoma, and various other intraocular disorders. While I have witnessed no late complications in such cases, for the simple reason that I have had no occasion to observe any adult or other patient in whom the Ziegler operation had been done, I take this opportunity to invite ophthalmic surgeons to report any data they may have which bears on this point.

For those who like to attempt to settle vexatious questions by citing authorities, reference will now be made to some comments on the Ziegler operation by several well-known ophthalmologists. The following statements were made at meetings of the Academy. One occasion was in 1926 during discussion of a paper by Dean;⁴ another was in 1928 when a paper by Wilder⁵ was being discussed. The Ziegler operation was disapproved by Dean, Greenwood, Lancaster, and Wilder, all of

whom stated that they were opposed to any traumatizing of the vitreous. Dean, in particular, questioned the validity of Ziegler's claim that his operation is never followed by increased tension. Benedict and Wiener, on the other hand, endorsed the Ziegler operation and saw no harm in the trauma to the vitreous incident to it. Benedict remarked that he could not see what difference it made whether the vitreous was incised at the first operation or the last.

Some of these discussants gave no particularly cogent reason why they approved or disapproved the Ziegler operation and its attendant trauma to the vitreous. Lancaster, however, in referring to one of his patients in whom an acute rise of tension followed the Ziegler operation and made it necessary to evacuate the lens material, remarked that the vitreous escaped more easily than the lens substance. Since that experience, he has not used the Ziegler procedure. Wilder believed that a marked delay in the absorption of the lens occurred when vitreous was allowed to mix with lens substance, as in the Ziegler operation. Ziegler himself, in his original report in 1921, stated that, while it was undesirable to "stir up" the vitreous, there would be no harm in making a clean cut incision into it with a sharp knife.

Nevertheless, it is an established fact that the vitreous breaks down as a result of direct trauma, to which it is very sensitive. Duke-Elder⁶ states: "The vitreous is a homogeneous gel in a very unstable state of dynamic equilibrium, the consistency of which can be readily destroyed by the slightest mechanical insult." E. Redslob⁷, who is internationally known for his work on the vitreous, in discussing the pathologic changes in the vitreous which arise solely from disturbance of the vitreous gel, states that a mechanical lesion, or trauma, is sufficient to cause a separation between the framework and

the liquid phase. In discussing disorganization of the vitreous by upset of the colloid equilibrium, he further states, under the heading of injuries of the eyeball: "Contusion may disorganize the vitreous structure. The same effect is produced by perforating wounds. In such cases, the bundles of agglutinated fibres converge toward the wound. This disorganization is readily observed when, following an accident or an operation, the vitreous body is extruded into the anterior chamber." As the eye pathologist can testify, the safest place for the vitreous is its normal habitat, and it does not stay there if one sticks a knife into it by way of the anterior chamber. No attempt will be made here to catalogue or describe the pathologic processes, some leading to secondary glaucoma, which may result from the prolapse of vitreous into the anterior chamber, a result virtually inherent in the Ziegler operation. It is sufficient to say that, in so far as cell growth plays a part in these processes, it is much more active in the young child than in the mature adult.

The idea that the vitreous must necessarily be incised in the discission of a thin membrane remaining after discission of the lens, as implied by Benedict in his statement already cited, is no more universally correct than it would be for discission of the thin membrane after extracapsular lens extraction. In brief, the posterior capsule of the lens is not necessarily in contact with the vitreous since, in most eyes, a true retrolental space exists. This space is still present if the posterior capsule has been preserved. By careful technique one can often incise the membrane without puncturing or incising the vitreous.

SUMMARY AND CONCLUSIONS

The surgical problems encountered in congenital cataract, especially in patients

between the ages of one and six years, have been discussed, and it has been proposed that an ideal method, contrary to most of the previously used methods, should obtain complete absorption of the lens nucleus and cortex, in the pupillary zone, within four to eight weeks, with a single operative procedure, and with only slight danger of undue reaction or increased tension. Furthermore, special emphasis has been placed on the importance of preoperative, maximal dilatation of the pupil, and upon the danger of incising the vitreous, either by accident or by design, as in the Ziegler operation. Linear extraction in this age group is disparaged, principally because of the danger of iris prolapse, although it is recognized that at later ages some form of extraction will be necessary. It is planned to deal with this subject in a subsequent paper.

The author's method of modified discission, in which the lens cortex and nucleus are divided into small fragments and these are then displaced, by means of the irrigator,* from the capsular sac into the anterior chamber is proposed as an approach to the ideal operative procedure for the age group cited. Although, to date, the method has only been applied in six eyes of three patients, the surgical results have been so uniformly good that it seems worth while to publish it. It is hoped that this method will be tried out by many operators in a large number of cases, for this is the only means by which a final evaluation of its true worth can be made.

Both a priori and judging from experience, there seems no need to postpone operation for congenital cataract beyond the age of two years, as a general policy; or, in bilateral cases, to interpose an artificial interval between operation on the first and second eyes.

ELECTROENCEPHALOGRAPHY AND OPHTHALMOLOGY*

ALSTON CALLAHAN, M.D.[†]*Birmingham, Alabama*

AND

FREDRICK C. REDLICH, M.D.[‡]*New Haven, Connecticut*

HISTORY

Electroencephalography is the technique of recording the electrical beat of the brain. The study of the electrical activity of the brain began in 1874 when Caton, an English scientist, discovered evidences of electrical fluctuations in the brain of living animals.¹³ In 1902 and 1907, Hans Berger, father of modern electroencephalography, recorded spontaneous rhythmical fluctuations in the electrical potentials from the brains of animals and, in 1930, was successful in recording evidence of the electrical activity of the human brain.⁷ He showed that normally the beat of the brain appears as a mixture of more or less sinusoidal fluctuation in voltage with a frequency of from 1 to 60 per second and that the most commonly recorded rhythm

has a frequency of approximately 10 per second in normal adults (fig. 1). Berger proved that this electric rhythm came from the cortex and called the record the electroencephalogram.

Gibbs and Gibbs,^{15, 16, 17, 18, 19} and William Lennox^{16, 28} have been the most prominent American investigators in this field, and their research has made this method of investigation useful in clinical neurology. Their work was greatly aided by the construction of a reliable and sturdy instrument by Grass, using magnetic inkwriters for the recording of the brain waves. Within the past 10 years, over 2,000 publications and some exhausting treatises on the subject of electroencephalography have been written. The outstanding reference is Gibbs and Gibbs's "Atlas of Electroencephalography,"¹⁵ which deals authoritatively with all aspects of clinical electroencephalography. Besides the numerous research publications, there are other excellent general references, such as Lindsley's,³¹ which stresses the physiologic and psy-

chologic aspects; Jasper's,^{22, 23} with its consideration of the epilepsy problem; and Hoefer's,²¹ Williams and Gibbs's⁵⁰ on the use of electroencephalography in the diagnosis and prognosis of head injury. The most important research on the localization of cerebral lesions was done by Walter,⁴⁹ and by Gibbs, Wegner, and

becomes faster and shallower with stimulation, and by attention. It becomes faster with increasing age. Electroencephalograms (EEG) vary considerably from one person to another and are not always constant in the same person.

Some confusion exists in EEG nomenclature, and many investigators now

Fig. 1 (Callahan and Redlich). Normal electrical rhythm of the brain. Tracings from four areas are made simultaneously. Monopolar lead.

Munro.^{18, 19} Berger's original articles remain the basic source of reference.

PHYSIOLOGY

The electroencephalogram records electrical brain activity from the surface of the scalp, just as the electrocardiogram records that of the heart from the chest wall. Voltage of the former is much smaller, however, being approximately one hundredth of that of the heart. Gibbs and Gibbs point to the similarity of the electrical rhythm of the cortex and the activity of the respiratory center; for example, respiration and brain waves (although 60 times faster than respiratory frequency) are both slowed considerably by sleep, sedatives, and low carbon-dioxide mixtures. The beating of the brain

avoid, wherever possible, the original designation of alpha, beta, or gamma waves. Gibbs has suggested a classification of waves based on their frequency, amplitude, and appearance. Normal frequencies in adults are from $8\frac{1}{2}$ to 12 per second; pathologic brain waves are classified as slow, very slow, fast, very fast, and paroxysmal, the latter occurring in a large percentage of convulsive disorders. The amplitude varies from 5 to 150 microvolts, the normal limits ranging from 10 to 50. The appearance is usually sinusoidal, but may be spike-like, or wave and spike, and similar combinations.

Like the electrocardiogram, the maximum diagnostic and prognostic value of the EEG is attained when it is combined with other types of clinical and laboratory examinations.

CLINICAL APPLICATION

Electroencephalography has become useful in neurologic diagnosis and has found widespread application. Its greatest usefulness lies in the following fields: (1) the diagnosis of convulsive disorders;⁴⁵ (2) the diagnosis and prognosis of head injuries, particularly those accompanied by convulsive seizures;²¹ (3) the

Fig. 2 (Callahan and Redlich). Position of leads for recording of electrical discharges from frontal, parietal, temporal, and occipital lobes. The lead on the ear is the "ground."

diagnosis and localization of expanding intracranial lesions, such as tumors, subdural hematomas, and brain abscesses;^{18,46} (4) the diagnosis of narcolepsy, of some types of encephalitis, and of the residuals of meningitis;⁴⁵ (5) it may be helpful in the diagnosis of diffuse, inflammatory, or degenerative conditions of the brain, in some organic psychoses, and it eventually may be of help in the diagnosis of personality disorders.³¹

TECHNIQUE

Small solder electrodes are affixed directly to the scalp without cutting or shaving the hair (fig. 2). The standard arrangement adopted in most laboratories,

including Army and Navy installations, is to use eight electrodes, with two ground electrodes attached to the ears (U. S. Army T.B. Med. Bulletin No. 74). For localization, ground electrodes are usually dispensed with, and the brain waves are recorded by the bipolar method. The electric current passes by conduction from the cortex through the skull and scalp to the solder electrodes, whence it goes to the switch box and to the amplifying units. The voltage of the brain waves is amplified about 10 million times, and the fluctuation is recorded on paper tape which moves past a recording point at a constant rate. Each lead is recorded separately, and on standard models, the brain waves from four to six channels may be recorded simultaneously. It requires 20 to 30 minutes to affix the electrodes, and the patient is instructed to lie on a cot or sit in a comfortable chair in a room properly screened from outside electrical interference. An EEG can usually be recorded in 30 minutes. We have employed the standard eight leads in studying certain eye problems, and in others we have affixed an electrode to each supraorbital region and (one) to each infraorbital region and used the bipolar method of recording.

APPLICATION OF ELECTROENCEPHALOGRAPHY TO OPHTHALMOLOGY

The aforementioned investigations are reported in special publications such as those of general biology, physiology, psychology, neurology, and psychiatry. Some have appeared in the general medical journals but very few in the ophthalmic literature.

Several problems of primary interest to ophthalmologists are: (1) local electrical discharges following eye opening and closing and eye movements; (2) effect of visual stimulation and eye opening and closing on the occipital electroencephalogram; (3) diagnosis of false

(hysterical or malingered) blindness; (4) localization of cerebral lesions with visual defects.

LOCAL ELECTRICAL DISCHARGES FOLLOWING EYE OPENINGS AND CLOSING, AND EYE MOVEMENTS

It has long been known that a constant electric-potential difference is present in the intact or enucleated eye, and that the cornea is always positive and the posterior half of the globe is negative. Adler¹ compares this to the demarcation current in the muscle of a frog's leg, and Duke-Elder¹⁴ believes that this difference in electrical potential is the registration of the difference in potentials which exist on either side of the membranes through which the intraocular fluid dialyzes. Miles^{36, 37, 38} has shown that the steady potential from the eyeball can be measured by making use of the eye's motility, electrodes being applied above, below, and lateral to the orbits. The measurable ocular polarity potential of the human eye *in situ* is in the order of 1.0 millivolt when the eye rotates laterally 30 degrees from the primary line of regard; the range between supposedly normal subjects is from about 0.3 to 2.5 millivolts. Mowrer, Ruch, and Miller³⁹ recorded potentials with a galvanometer, and since they were able to abolish them by destruction of the retina of rabbits with hydrochloric acid, considered them due to the corneoretinal potential. Redlich, Callahan, and Schmetje⁴³ have examined 40 patients (table 1) with various injuries and diseases of the eye, recording the electric potentials from supraorbital and infraorbital leads with the electroencephalographic apparatus. (These fluctuations are from the eye potential, and are not brain waves.)

Eye opening and closing, or blinking. The blink reflex is a sudden, firm closure of the lids, in which the superior rectus

contracts to pull the eye up, the levator relaxes, and the orbicularis contracts firmly to close the lids.

In patients with normal visual apparatus, blinking of the eye caused 2- to 4-per-second sinusoidal waves of 60 to 150 microvoltage, seen best in the frontal leads, occasionally in the other leads.

TABLE 1
TYPES AND DISTRIBUTION OF OCULAR LESIONS
USED FOR EXPERIMENT

Unilateral traumatic anophthalmos (operative enucleation)	16
Unilateral traumatic anophthalmos (operative evisceration)	10
Bilateral enucleation	1
Bilateral evisceration	1

Unilateral optic atrophy with amaurosis	2
Unilateral avulsion of the optic nerve	2
Unilateral traumatic chorioretinitis	2
Unilateral optic neuritis, cause unknown	2
Total	40

They are regular, smooth, and differ radically in their appearance from muscle-potential discharges, which result from action of the palpebral, orbicular, frontal, and temporal musculature.

In patients with unilateral anophthalmos (enucleations and eviscerations), the potential from the anophthalmic side was either very weak or absent (fig. 3). When present, it is probably due to the spread of potentials from the normal side. No blink waves were seen in a case of bilateral evisceration or in a case of bilateral enucleation.

In patients with unilateral optic neuritis and extensive chorioretinitis, the potentials following blinking were of a similar nature and order from both affected and normal eyes. Normal blink waves were obtained in the complete absence of light perception.

Eye movements. Lateral and vertical spontaneous and voluntary eye move-

ments result in only small deflections as recorded on the electroencephalogram, and they are identical with those obtained when the eyeball is moved passively with a forceps. In patients with a unilateral evisceration or enucleation, no potentials

not due to muscle currents. This finding is in corroboration of the work of Miles and Mowrer, Ruch and Miller.

In addition to the steady potential of the eye, an action current is formed when light falls on the retina. This current

Fig. 3 (Callahan and Redlich). Patient 446; left eye has been eviscerated. Leads were placed at the orbital rim of each side, and the patient was instructed to blink eyelids rapidly. The large sinusoidal waves as recorded from the right orbit are the so-called "blink waves." This finding suggests that the retina is essential for movement discharges.

Fig. 4 (Callahan and Redlich). Patient 597; left eye has been eviscerated. Leads placed at orbital rim of each side, and patient instructed to roll his eyes about. This finding also suggests that the retina is essential for movement discharges.

were observed on the injured side after active or passive eye movements (fig. 4). In patients with optic neuritis and chorioretinitis, there were normal potentials after eye movements. Studies of the electrical component of nystagmus have been made but no typical electrical phenomena could be recorded on the electroencephalogram upon eliciting optokinetic nystagmus in normal eyes.

Therefore, it seems quite certain that the electrical potentials which occur are due to the corneoretinal potential, and are

can be registered in the form of an electroretinogram, which shows the short latent period after the stimulus and then a short negative phase followed by the sharp, large, positive deflection that subsides slightly and is succeeded by a much slower, longer, positive phase. The optic nerve, although a part of the central nervous system, responds to stimulation remarkably like a sensory nerve. The latent period after stimulation of light is considerably longer than the latent period of retinal current, and Adrian found that

the latent period could be considerably shortened by increasing the size of the retinal image, which implies that the various points in the retina are linked together. There has been considerable scientific interest in the phenomenon of the eye's photoelectric response to light, but in none of our studies did we record electroretinograms, and it is mentioned only as a preliminary to consideration of the following sections, which deal with

cedures which stimulate the subject result in a change of the occipital rhythm.

Redlich, Callahan, and Mendelsohn⁴⁴ found, in a study of 30 patients with normal brain waves, that opening the eyes in complete darkness or in a lighted room usually had about the same effect, although the rhythm returned to the pre-stimulation rate more quickly in the dark than when the eye was opened in daylight (fig. 5). This suggests the exist-

Fig. 5 (Callahan and Redlich). Patient 869; no abnormality of visual mechanism. A, EEG tracing in daylight. B, EEG tracing in darkness are identical except for quicker return of original (closed-eye) rhythm in darkness. Monopolar lead.

the resultant effects upon the cerebral cortex of the action of light upon the retina.

EFFECT OF VISUAL STIMULATION ON THE OCCIPITAL RHYTHM

(1) *Single visual stimuli, by eye opening and closing.* Berger^{7, 8} reported that visual stimulation by the opening of the eyes in a lighted room altered the occipital-brain rhythm, but that opening of the eyes in a darkened room did not change it.

Jasper and Cruikshank^{22, 23} found an increase in frequency of the brain waves after opening the eyes in a lighted room but mentioned that sometimes opening of the eyes in the dark produced similar results. Williams⁵¹ showed that not only visual stimulation but other pro-

ence of additional factors besides the stimulus of light on the retina in the production of altered occipital rhythm. It is unlikely that the factor of attention alone accounts for this, for only 9 of 42 patients showed changes when, with eyes closed, they were asked to visualize some person or object.²⁰

Changes of the occipital rhythm after visual stimulation caused by the opening and closing of eyes in daylight were studied in 100 patients with normal vision, 32 patients with unilateral blindness, 3 blind patients, and 9 patients with homonymous hemianopia.

In 10 of 11 patients with unilateral blindness (enucleation) and with normal electroencephalographic rhythm, opening of the lid of the anophthalmic side had about the same effect on the occipital

rhythm as opening the eye on the normal side.

No changes in the occipital rhythm after opening the eye were noted in three patients with normal alpha rhythm, who were blind because of bilateral exsiccation or enucleation.

We attempted to discover some characteristic EEG finding in amblyopia ex anopsia. In 10 such patients whose records we studied, the occipital rhythm was normal, and there was no difference in the occipital waves when the normal and when the amblyopic eye was stimulated in turn by a weak light, a bright light, by reading, and by reviewing a picture.

(2) *Repeated visual stimuli.* Although other investigators have previously noted that repetitive photic stimulation of the retina induced changes of the occipital waves, Adrian and Matthews² were the first to use photic driving to modify the normal occipital rhythm. They found that photic driving in man was most apparent when the rate of photic stimulation was between 10 and 20 cycles per second. Synchronous records of the occipital and temporal alpha rhythm show that the occipital alpha waves can thus be made to follow a flickering light; whereas, the frontal alpha waves retain their original rhythm and are unaffected by it.

Bartley,^{3,4,5} Bartley and Bishop,^{6,9} and Bishop and O'Leary^{10,11,40} showed that response to controlled stimulation of the retina or the optic nerve emerges in the cortical record as a quite definite wave complex. To insure the most condensed response by eliminating the complications due to repeated sense-cell discharge, in the experiments of Bishop and O'Leary the optic nerve was stimulated directly. They found that the stimulus drives the cortex by instituting a series of waves which are similar to alpha waves but out of phase with the preëxisting alpha waves

and sometimes entirely supplanting them. It is, therefore, possible that the peripherally induced cortical activity and the preëxisting waves occupy the same group of cells in the same way and that direct stimulation may initiate an alpha rhythm.

USE OF THE ELECTROENCEPHALOGRAM IN DISTINGUISHING TRUE FROM FALSE BLINDNESS

The fact that most individuals with normal visual systems will show EEG changes upon opening the eyes has led Lemere²⁷ to conclude (unjustifiably) that it is a method of differentiating true from false blindness with certainty.

TABLE 2
CHANGES IN THE OCCIPITAL RHYTHM FOLLOWING
OPENING OF THE EYES IN DAYLIGHT

	Amplitude	Frequency
No change	12	20*
Slight change	16	51
Moderate change	31	10
Marked change	41	19

* All 12 of the cases showing no change in amplitude are in this group of 20.

As stated previously, the effect on occipital rhythm of visual stimulation caused by opening and closing the eyes in daylight were studied in 100 patients with normal vision. The findings are shown in Table 2. From these, it is evident that most persons with normal occipital rhythm and with normal visual apparatus do show changes in the occipital rhythm when the eye is stimulated by light; but it is also evident that there are exceptions (fig. 6). Therefore, the effect on the EEG caused by opening and closing the eyes does not permit a consistently valid differentiation between true and false (hysterical and malingered) blindness, and this method of testing has no medico-legal value.

However, it was observed that the moderate and marked changes in ampli-

tude and frequency occurred mostly in patients with a well-defined, regular occipital rhythm of about 10-per-second frequency. The same was true, although less marked, in the slow groups. In many patients with fast rhythms, the changes after opening the eyes were usually less pronounced or absent. Abnormal waves of diagnostic significance in epilepsy and similar affections showed a tendency to disappear after the eye was opened; after a few moments, some would reappear. But

This consists of stimulating the eye with a powerful source* of light and recording the galvanic skin response with a Grass electroencephalograph. The galvanic skin response is the bioelectric current accompanying sweat-gland and vasomotor activity induced by sensory stimuli, attention, and various types of psychologic situations. Landis²⁵ has reviewed the various methods used. A new method of recording it with the EEG has been described by Redlich,⁴¹ in order to differ-

Fig. 6 (Callahan and Redlich). Patient 204; no abnormality of visual mechanisms. Eye opening causes no appreciable change in rhythm or amplitude.

in general, open-eye records were of much less diagnostic aid than was the standard record with the patient's eyes closed.

In 42 patients, we recorded normal EEG changes after the eyes were opened. A card was then held before the patient, and he was asked to read. In 13 of these patients, changes were more marked and more lasting than the changes after the eyes were opened, and in the other 29 they were relatively the same. This variance makes it difficult to arrive at any conclusion in regard to EEG changes with varying use of the eyes. Nor did we find a difference in the normal occipital rhythm after stimulation of the normal eye and fellow eye with advanced pathologic change (such as massive chorioretinitis or optic atrophy).

In a different set of studies, we have used the EEG as a test of light perception to differentiate true from false blindness.

entiate organic from hysterical anesthesia in patients with traumatic injuries of peripheral nerves and spinal cord.

Our tests were carried out in a completely darkened room with the patient resting on a bed. The bioelectric currents were obtained from one solder electrode fastened to the palm with adhesive tape and another electrode attached over a scratched area of skin of the forearm. Bipolar recording was used. Attenuations were set from 7 to 10 on the scale. Low-frequency filters were set on M, and high-frequency filters on four. The tracing was a fairly straight line. After stimulation of the eye with an intense light, a deflection was noted when visual perception was present. The same stimulation of the totally blind eye induced no response (fig. 7).

*3,000 foot-candles on the eye at a distance of 3 feet.

We examined 26 patients with unilateral blindness and were able to obtain a response from the normal eye in all cases; whereas, no response was obtained after visual stimulation of the blind eye. We did not have the opportunity to observe patients with hysterical or malingered blindness. But, from the work of Levine,^{29, 30} and Marquis and Williams,³⁴ it is to be expected that visual stimulation of a patient with hysterical or malingered blindness would elicit a nor-

ported a series of five brain tumors involving the optic pathway. In each of the cases, there was a loss of normal occipital rhythm over the affected area. Traumatic homonymous hemianopia was studied by Redlich, Callahan, and Mendelsohn.⁴⁴ They reported 12 patients with injury to the parietal, temporal, and occipital lobes with residual hemianopia or quadrianopia to have the following responses: Focal abnormalities were present in seven; generalized EEG abnormalities in three; and

Fig. 7 (Callahan and Redlich). Patient 818; left eye completely blind due to traumatic retinal hemorrhage; right eye normal. Galvanic skin response recorded with electroencephalograph after stimulation of normal and blind eye with 3,000 foot-candles at 3 ft. Monopolar lead.

mal GSR, and thus this method would permit differentiation of organic and psychogenic blindness.

LOCALIZATION OF CEREBRAL LESIONS WITH VISUAL DEFECTS

When a lead is placed near cerebral lesions, such as neoplasms or encephalomalacias, which are superficial in location, the waves from this area are generally slow, and if recorded by the localizing bipolar method, can be shown to be "out of phase." By these characteristics, it is possible to determine the approximate location of a superficial lesion (figs. 8 and 9.) In very extensive destruction of cerebral tissue, no brain waves can be recorded at all.

Homonymous hemianopia caused by tumors were studied by Case,¹² who re-

ported a series of five brain tumors involving the optic pathway. In each of the cases, there was a loss of normal occipital rhythm over the affected area. Traumatic homonymous hemianopia was studied by Redlich, Callahan, and Mendelsohn.⁴⁴ They reported 12 patients with injury to the parietal, temporal, and occipital lobes with residual hemianopia or quadrianopia to have the following responses: Focal abnormalities were present in seven; generalized EEG abnormalities in three; and

SUMMARY

1. A brief résumé of the history of electroencephalography are presented.
2. Some of the physiologic facts of electroencephalography are presented.
3. The clinical use of the electroencephalogram in neurologic diagnosis is outlined, especially as it concerns various convulsive disorders and localization of

Fig. 8 (Callahan and Redlich). Patient 773. Standard leads. Slow-wave focus in left frontal area. Clinical and pathologic diagnosis: astrocytoma of the left cerebral hemisphere. Monopolar lead.

Fig. 9 (Callahan and Redlich). Patient 232; right temporal lobe injured by shell fragment, with left homonymous hemianopsia. EEG shows slow-wave focus in right temporal area. Monopolar lead.

focal cerebral lesions.

4. The technique of recording an electroencephalogram is described.

5. The application of electroencephalography to ophthalmology is discussed as follows:

(A) The use of the EEG to record changes of electrical eye potentials following eye movements. These potentials can be observed only when the retina is present and are thought to be due to the corneoretinal potential difference.

(B) The effect of visual stimulation and the opening and closing of eyes was studied in 100 patients, and an incon-

clusive statistical scatter of findings resulted. In investigating the effect of the visual stimulus on the normal occipital rhythm, we found, in a study of 30 patients with normal brain waves, that opening and closing the eyes in the dark and in the light had similar effects. The normal occipital wave in man can be driven by repetitive photic stimulation of the retina. No characteristic finding was discovered in 10 cases of amblyopia.

(C) The effect of opening the eye on the normal occipital rhythm does not differentiate true from malingered or hysterical blindness.

(D) We have employed the electroencephalogram to record the galvanic skin response after visual stimulation and, in this manner, true blindness can be differentiated from false blindness.

(E) The electroencephalogram is an aid in localizing cerebral lesions with visual defects. Superficial lesions, especially tumors, frequently show slow waves.

DISCUSSION

DR. CLYDE A. CLAPP (Baltimore, Maryland): Dr. David Harrington wishes to know: "Was there any correlation between the EEG finding and congruity of the visual fields in antero-posterior localization of cerebral lesions?"

DR. CALLAHAN (closing): The question refers to the hypothesis that the more posterior the lesion is located, the more

congruent are the field defects, and Dr. Harrington wishes to know if we found evidence to support or disprove this theory. We did not make a study of our cases for this relationship. Case has reported seven cases of homonymous hemianopsia, proved at surgery to have tumors of the optic tract, which showed a loss of normal occipital rhythm over the occipital cortex.

HEREDITARY NYSTAGMUS OCCURRING AS A SEX-LINKED CHARACTER RECESSIVE IN THE FEMALE*

C. WILBUR RUCKER, M.D.
Rochester, Minnesota

Hereditary nystagmus appears as a constant, horizontal, to-and-fro movement of the eyes, pendular in type, at the rate of about 120 beats per minute, of small excursion on forward gaze and coarser on looking to the sides. Even among members of the same family it varies somewhat in rate and amplitude; it may show a quick component on lateral gaze, and may be more pronounced on turning the eyes to one side than when they are turned to the other. Visual acuity is usually fairly good, generally 20/30 to 20/50, in spite of the constant motion of the eyes, and would probably be still better if only the eyes could be made to stand still. Reduction in visual acuity seems not to be the cause of the eye movements, yet the nystagmus is somewhat similar to that resulting from defective vision.

Hereditary nystagmus must be distinguished from nystagmus due to such conditions as congenital cataracts, corneal scars, macular lesions, and albinism. In all of these conditions, visual acuity is reduced for reasons evident to the examiner. In hereditary nystagmus, the eyeballs are normal, and there is no significant refractive error. In some cases, there is an accompanying shaking of the patient's head.

Nystagmus is said to be inherited in any one of several different ways—as a Mendelian dominant or recessive character, or as a sex-linked character. In most reported families, it seems to be transmitted in a partially sex-linked fashion, as in the first family described in

Nettleship's¹ paper in 1911. In that author's second family, it was transmitted as a sex-linked character entirely recessive in the female, as it was in the cases to be reported herein. The literature contains descriptions of relatively few families of this latter type, one of them being that of Waggoner and Boyd² published in 1942. Since these authors appended a list of pertinent references to their report, its repetition is unnecessary here.

REPORT OF CASES

The propositus of the family to be reported herein was a 7-year-old boy (individual 27 in generation VI in figure 1) whose father brought him to the Clinic to have an operation performed on his eyes to steady them. The father stated that ever since the boy's birth his eyes had been in constant motion. On examination there was apparent a small, rapid, horizontal, pendular nystagmus. When the boy turned his eyes beyond 20 degrees to each side, the movements became coarse and less rapid. The refractive error was slight. Visual acuity could not be determined accurately because the boy had not attended school and was shy, but it was definitely better than 20/70.

The father said he had another son (individual 30 in generation VI in figure 1) aged two years, who was similarly afflicted. The nystagmus had been noted "at birth." On examination of this 2-year-old boy a short time later, I found that his condition resembled that exhibited by individual 27 in generation VI. Neither of these boys showed any shaking of the head.

The father said that these boys had a

* From the Section on Ophthalmology, Mayo Clinic.

cousin (individual 24 in generation VI in figure 1), the son of a sister of the boys' mother, who had the same sort of trouble with his eyes. I found that the cousin in question was 7 years of age and that the movement of his eyes had been first discovered by his parents when he was six months old. Nystagmus on forward gaze was horizontal and pendular, small

nystagmus. These cousins were sons of another sister of the mother of individuals 27 and 30. Since these two cousins lived several hundred miles away, I had to rely on their mother for a description of their eyes. Individual 19 in generation VI in figure 1, now a boy 10 years of age, has eyes that have been "terribly active" since the age of three months, when he had

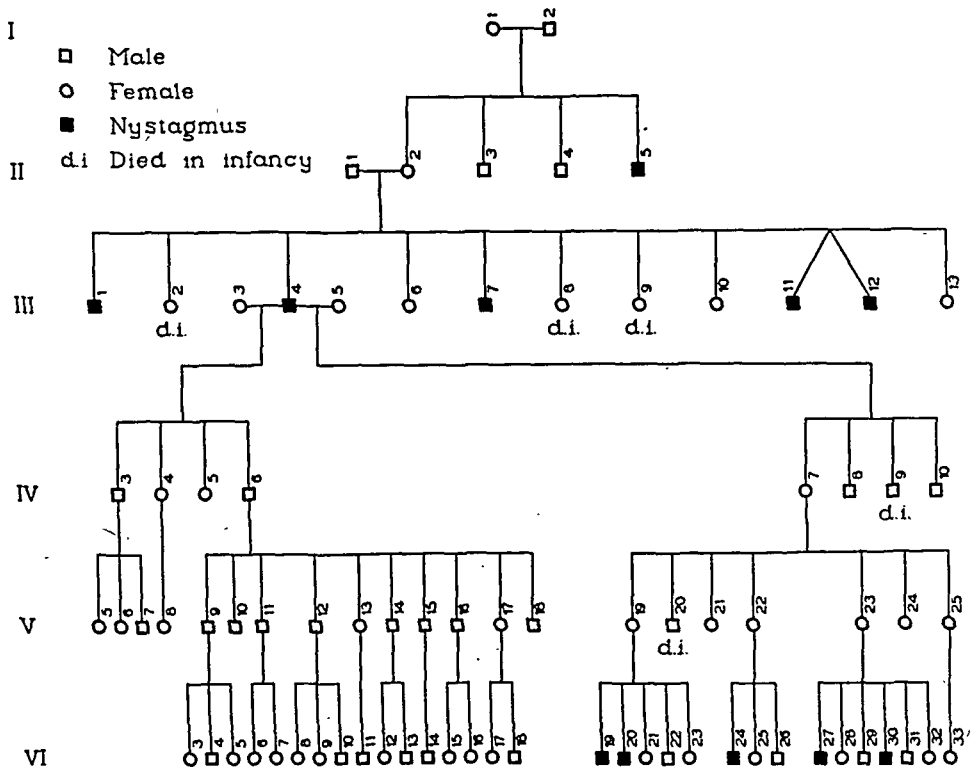

Fig. 1 (Rucker). Genealogic tree showing descendants of individual 4 in generation III. This individual was married twice (to individuals 3 and 5 in generation III).

in amplitude, and coarse on the patient's looking to the sides. Its rate was about 120 beats per minute, although at times it stopped altogether. There was an accompanying side-to-side shaking of the head, a negation movement, not synchronous with the eye movements. The jerking of the head and eyes was thought by the parents to be lessening, but became pronounced when the boy was tired. Visual acuity was 20/30 in each eye.

The two boys first mentioned (individuals 27 and 30 in generation VI in figure 1) had two other cousins who also had

pneumonia. Individual 20 in generation VI in figure 1, an 8-year-old boy, also has "jerky eyes," first noticed at the age of 6 years, when he had measles.

I examined most of the brothers and sisters of these afflicted boys, and their parents and some of their grandparents, without encountering any further evidence of nystagmus. Not until I examined the half brother (individual 6 in generation IV of figure 1) of the grandmother of the nystagmic boys did I obtain further clues. This half brother himself had normal eyes, as did all his children and

grandchildren (fig. 1), many of whom I examined personally. This half brother, however, told me that his father had the type of jerking of the eyes that I was seeking. With that clue, it became possible to work out the complete family tree.

The father (individual 4 in generation

they, too, were born with nystagmus. Although I have no information about this brother's parents (individuals 1 and 2 in generation I in figure 1) except their names and dates of birth, it will become apparent, after their descendants have been traced, that they must have had nor-

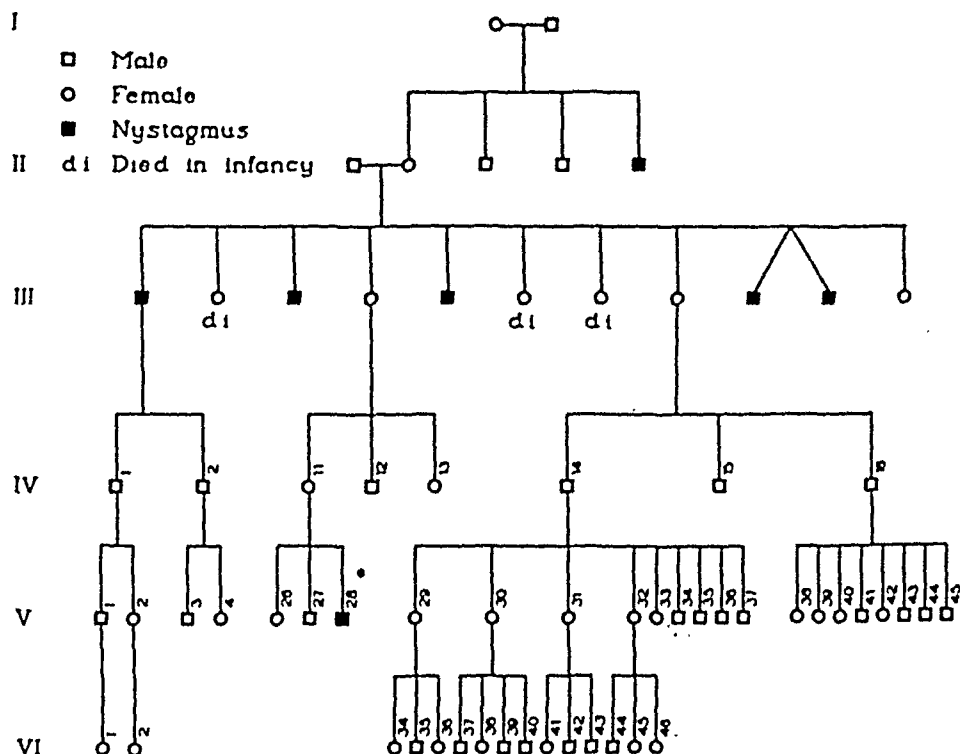

Fig. 2 (Rucker). Descendants of additional members of generation III: those numbered 1, 6, and 10 in figure 1. Generations I, II, and III are repeated.

III in figure 1) of this half brother had been married twice. He had 10 brothers and sisters. Every one of his four brothers had nystagmus, whereas all of his sisters were free of it. Their parents (individuals 1 and 2 in generation II in figure 1) had normal eyes, but their mother had a brother (individual 5 in generation II in figure 1), who had nystagmus. This is confirmed by a story in the family that this brother (individual 5 in generation II in figure 1) was visiting his sister shortly before she was delivered of the twins (individuals 11 and 12 in generation III in figure 1), and that "he cast his mark on them," with the result that

mal eyes and that the mother (individual 1 in generation I in figure 1) was a carrier.

In figure 2, the eldest male in generation III is said by all who knew him to have had constant side-to-side shaking of his eyes and his head. He had two sons (individuals 1 and 2 in generation IV in figure 2), both of whom had normal eyes, as have all of their descendants.

In generation III (fig. 2), the eldest surviving female had normal eyes, and left three children, only one of whom, a daughter (individual 11 in generation IV), married. She has three children, (individuals 26, 27, and 28 in generation

V in figure 2). Individual 28 is a 15-year-old boy who has nystagmus. Although I have not as yet examined him, I have notes made by an ophthalmologist who saw him when the boy was 6 years old. The notes state that the boy has a "searching type" of nystagmus, no significant re-

The female next to the youngest in generation III bore three sons (individuals 14, 15, and 16 in figure 2), all of whom have normal eyes, as do all of their descendants (fig. 2).

In figure 3 are shown the descendants of "the twins," the youngest males of gen-

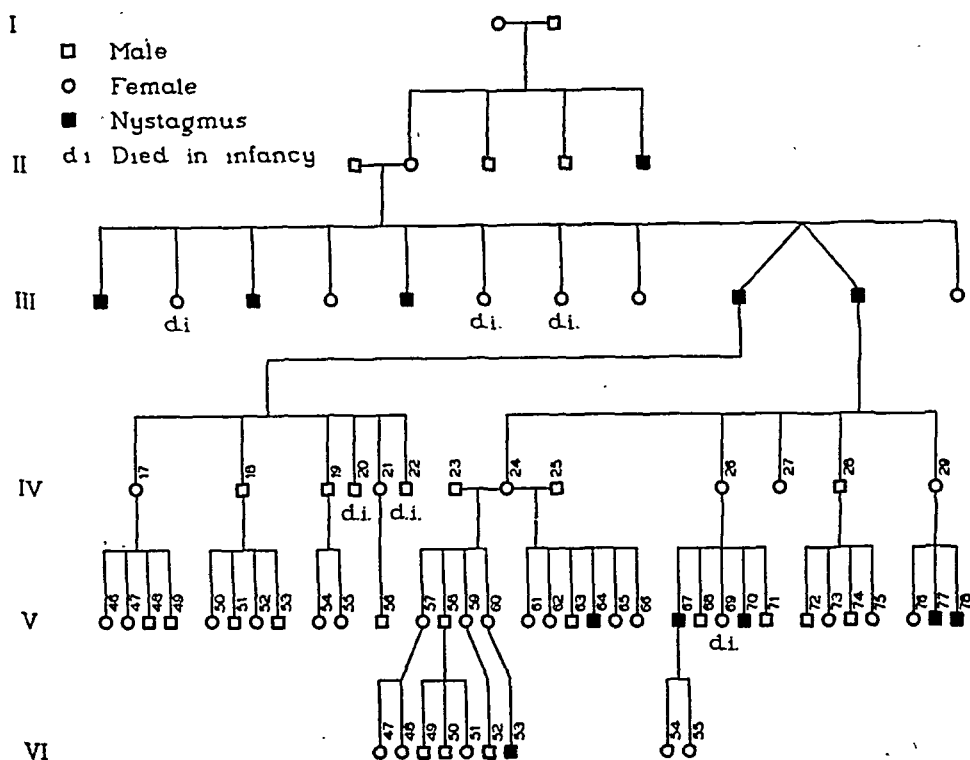

Fig. 3 (Rucker). The descendants of individuals 11 and 12 in generation III in figure 1. These individuals are twins.

fractive error, and that he holds his head to one side when reading. By referring to figure 2, it can be seen that the gene for nystagmus which this boy received passed through four female carriers, all of whom had normal eyes. Not one of his direct ancestors through these four generations exhibited nystagmus, yet he has, without question, an inherited disease.

The third male in generation III (fig. 2), who died at the age of 48 years, is said to have had nystagmus which became more pronounced as he grew older. I do not know whether he had a tremor of the head or not. He left no descendants.

eration III (individuals 11 and 12 in generation III in figure 1). They both dislike physicians so thoroughly that I have been advised not to attempt to examine them. All who have seen them report that both have nystagmus and also constant shaking of the head. One is said to carry his head bent toward his left shoulder, and the head of the other man is reported to be bent toward his right.

The first of the twins has no nystagmic descendants. The second twin has four daughters (individuals 24, 26, 27, and 29 in generation IV in figure 3), all of whom have normal eyes. Of the three daughters

who have married, each has one son or two sons who have nystagmus (individuals 64, 67, 70, 77, and 78 in generation V in figure 3). The eldest daughter (individual 24 in generation IV in figure 3) has a grandson (individual 53 in generation VI in figure 3), a 2-year-old boy, who has constant horizontal nystagmus which becomes coarse on his looking to

with the right eye and 20/50 with the left. With each eye, he can read 14/21 on the American Medical Association reading card. He spent three years during World War II in the supply department of the Army Air Forces.

Individual 70 in generation V in figure 3 is a younger brother of individual 67 of the same generation. He is now 20 years

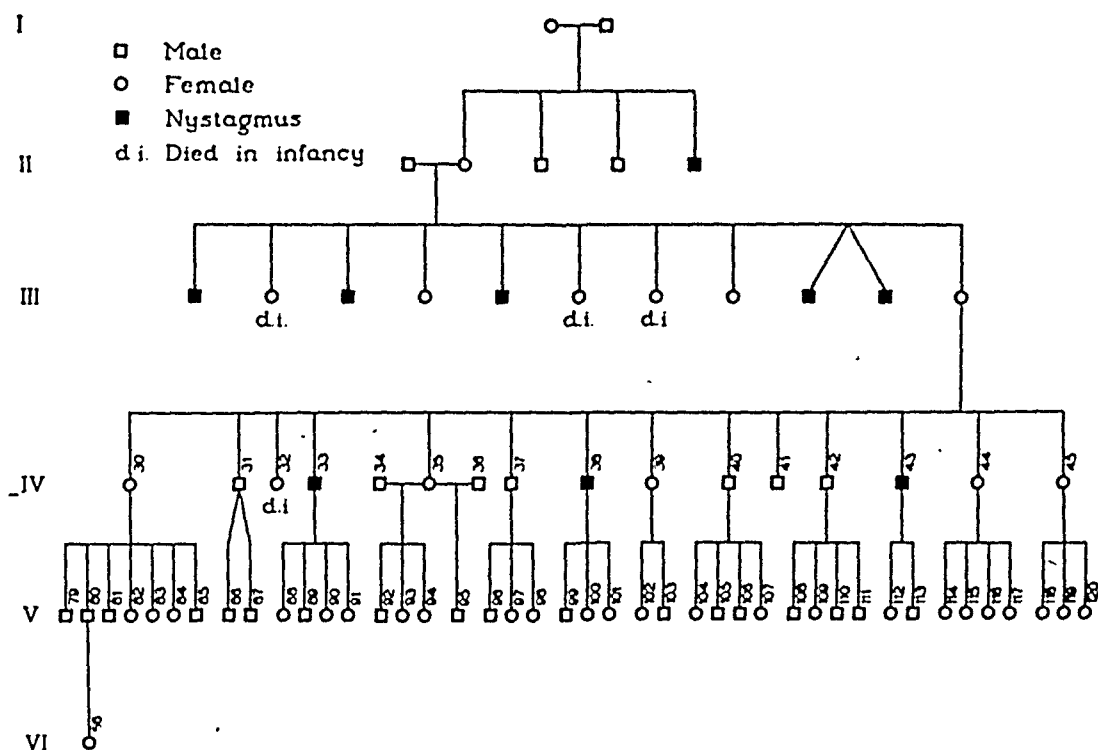

Fig. 4 (Rucker). The descendants of individual 13 of generation III in figure 1.

the left, and diminishes on his looking to the right.

Individual 64 in generation V in figure 3, a 5-year-old boy, has nystagmus, his mother says, only when he is tired or angry.

Individual 67 in generation V in figure 3 is a 25-year-old man who has a pendular, horizontal nystagmus. The movements are short and quick on forward gaze. When this man reads for a time the movements become greater, and a small head jerk appears. Visual acuity is 20/70

of age. He has a horizontal pendular nystagmus. The movements have a small range on his forward gaze, and become coarse on his looking to the sides, more so when he looks to the right than when he looks to the left. When he reads, he tilts the head to the left. There is no tremor of the head. In spite of the nystagmus and several diopters of myopia, his visual acuity with correction is 20/45 in the right eye and 20/40 in the left. He reads 14/14 on the American Medical Association reading card with each eye. He spent

six months of World War II in the Navy, and was discharged because of his ocular trouble.

Individual 77, aged 5 years, and individual 78, aged 1 year, both of generation V in figure 3, are brothers who, their mother says, are afflicted badly with the jerky eyes possessed by several of her relatives.

The only son of the second twin is individual 28 in generation IV in figure 3. He has four children, all of whom have normal eyes.

As shown in figure 4, the youngest female of generation III bore 14 children. Her five daughters have normal eyes; a sixth daughter who died in infancy also had normal eyes. Of her eight sons, three are nystagmic. As yet, none of her grandchildren has shown evidence of nystagmus. The explanation may be that her eldest daughter (individual 30 in generation IV in figure 4), who is the only one with many children, may happen not to be a carrier; and her two youngest daughters (individuals 44 and 45 in generation IV in figure 4) have given birth only to girls. Twenty-two of her 42 grandchildren are offspring of her two sons and would not be expected to be nystagmic.

The first son of this youngest female in generation III to show nystagmus was individual 33 in generation IV of figure 4, a man now 42 years of age. His eye movements are horizontal and pendular. His vision, with correction of one diopter of astigmatism in each eye, is 20/40.

Individual 38 in generation IV in figure 4 is now 37 years of age. His eyes have a constant pendular motion, about 100 beats a minute, which is a slower rhythm than that shown by most of his relatives whom I have examined. As in the case of the others, the movements on looking to either side become coarse. On the American Medical Association reading card he

reads 14/24 with his right eye, and 14/35 with his left. His shuffling gait and clumsy behavior suggest that his neurologic disturbance may not be limited to his eyes.

Individual 43 in generation IV in figure 4, a man 28 years old, is said by members of his family to have a "slight jerking" of his eyes. I have not examined him.

COMMENT

In this family tree in which there are 231 members in 6 generations, 21 individuals had nystagmus. All were males, and all inherited it through females who themselves were not affected. In a number of instances, the gene passed through a chain of several females before it became evident in a male descendant. In no case has a male transmitted the defect to his son. All descendants of nonaffected males are free from the defect. In this family, then, the character is sex-linked, and without exception has been recessive in the females. Its gene is carried in an X-chromosome, as is the gene for hemophilia and that for red-green color blindness.

Nettleship, on the basis of his observations, concluded that in families in which nystagmus was inherited as a sex-linked character, recessive in the female, associated head movements occurred rarely, and that in families in which both males and females were affected, head movements were common. This has not been my experience, for in the family reported herein a considerable number of the nystagmic persons did have associated head movements. Furthermore, in some of my unreported families in which the mode of inheritance is different from that encountered in the present family, I find head movements uncommon. The manner of inheritance seems not to be related to associated head movements.

Waggoner and Boyd in their report called attention to the frequency of associated neurologic disturbances. These were present in a few of the members of the family reported on herein, but could not be classified for want of neurologic examinations. Most of the nystagmic persons seemed to be free from other disturbances, so far as I could judge from their actions. If a competent neurologist had had the opportunity to examine all

had had time to develop. At present, it seems futile to try to guess where within the central nervous system the disturbance lies.

With a complete family tree available, and with the knowledge that in every instance the nystagmus has been inherited as a sex-linked character, recessive in the female, it is now possible to give reliable advice to members of this family. Several have sought such advice and have

Fig. 5 (Rucker). Diagram of the mode of inheritance of a sex-linked characteristic which is recessive in the female.

members of this family, he might have been able to find some type of disturbance associated with the nystagmus, for the difficulty appears to lie in the central nervous system. Neither albinism, nor high refractive error, nor defective visual acuity can account for the nystagmus, because these conditions were absent in most cases. Furthermore, several mothers were certain that the nystagmus had been present at birth or within a few days thereafter. Since the macula is not completely differentiated until about four months after birth, and evidence of fixation is not present until about the same time, the nystagmus could not have been dependent on any derangement of vision, because it appeared before visual acuity

been grateful for it. As an aid in explaining the transmission of a sex-linked character, the simple diagram reproduced in figure 5 was drawn. It shows that all the children of an affected male will have normal eyes, but that the daughters will transmit the defect to half of their sons. It is well for nystagmic persons to know this. The diagram also shows that all the descendants of normal males are free from this condition, a fact which has given comfort to several such members who feared they might have nystagmic children.

It is unfortunate that in the human race a single characteristic can be transmitted in one of several different ways. Often, one is able to predict the future course of

a hereditary defect only after studying the transmission of that defect through several generations of a family. Once the mode of transmission is known, however,

the future is clear and certain, and the physician is in a position to give helpful advice to members of that family.

THE INFLUENCE OF BARBITURATE ON VARIOUS FORMS OF NYSTAGMUS*

One of the signs of mild barbiturate intoxication is nystagmus. This is apparent when the patient turns his eyes on command or when he attempts to look in any direction. Any movement of the globes from the mid position is accompanied by nystagmus. The patient is also unable to maintain his eyes in a deviated position. Apparently, barbiturate in sufficient concentration interferes with normal ocular movement in man.¹ Barbiturates also influence eye movements in cats.² According to Spiegel and Collins,³ the ocular effects (rotation of eyes) are produced by the action of the drug on the brain stem. They suggested that barbiturate anesthesia causes a disequilibrium between the right and left vestibular nuclei and consequent homonymous rotation of the eyes. From their experiments, however, changes in the position of the eyes produced by barbiturate are due not only to the action of the drug on the central vestibular mechanism, but to action on other parts of the brain as well.

* From the U. S. Naval Hospital. The opinions and views set forth in this article are those of the writers and are not to be construed as reflecting the policies of the Navy Department.

The object of this investigation was to determine what effect the barbiturate had on nystagmus and the ocular movements in man. Patients with lesions of the peripheral vestibular apparatus, brain stem, or cerebrum were studied. In addition to this group, patients with various forms of nystagmus were examined after they had been injected with sodium amytal. When possible, the effects produced by intravenous injection of sodium amytal were correlated with the clinically determined lesion. In some instances, however, the nature and location of the pathologic process could not be ascertained, but since the cases revealed what seemed to be pertinent data, they were included in this study. To make the investigation more complete, we also included a series of psychiatric patients who showed no true physical defects and who were given intravenous injections of sodium amytal (narco-analysis and narco-synthesis).†

† Since these patients showed no signs of organic disease (specifically of the visual, oculomotor, or vestibular systems) we considered them as a normal control series. Those individuals who showed hysterical ocular palsies were classified in the pathologic group.

METHOD

Before the administration of the drug, all the patients were examined from the neurologic standpoint. They were also tested with the striped drum for the presence of opticomotor nystagmus.⁴ The alternately black and white stripes, one-half inch in width, were situated on the curved surface of a cylindrical drum, 8 inches in diameter and 10 inches high. The drum was slowly rotated with its axis either in the vertical or horizontal plane, and the patient was instructed to watch the moving stripes in the center of the drum. In the normal individual, this procedure yields a nystagmus known as opticomotor or the "optokinetic" type.⁵ In many instances, these preliminary studies were augmented by Bárány turning, and caloric and galvanic stimulation tests of the semicircular canals. The drugs administered were sodium amytal, sodium pentothal, and sodium luminal. In most cases, however, sodium amytal was used. The drug was injected into the antecubital vein at a rate of 0.1 gm. per minute for a total of 0.3 to 0.5 gm. The patient was seated and engaged in conversation so as to prevent his falling asleep. He was repeatedly asked to accomplish simple tasks which required his visual attention. The ocular findings were recorded chronologically in minutes.

RESULTS

I. NORMAL GROUP

From two to three minutes after the injection of the drug, a slow and coarse nystagmus was observed when the patient attempted to turn his eyes in any one direction. The nystagmus fluctuated in amplitude and rate of ocular excursions. The change occurred every 90 to 120 seconds and was evident during ocular deviation in the horizontal plane. At one period, the nystagmus was more pro-

nounced on right lateral gaze, whereas at another time (90 to 120 seconds later), it was most manifest with the eyes in the left lateral positions.

Opticomotor nystagmus induced by the rotation of a striped drum was invariably abolished about two minutes after the administration of the drug. This physiologic nystagmus remained absent for two and sometimes three hours, even though the patient (a) had a small dose (0.1 gm. of drug), (b) his attention was intact, and (c) his convergence power was preserved.

Comment. All of these findings were consistently present in every normal individual tested. They show that (a) barbiturates produce a nystagmus which seems to fluctuate periodically and is most apparent during ocular deviation, and (b) barbiturate abolishes reflex opticomotor nystagmus.

II. PATIENTS WITH LESIONS OF THE VESTIBULAR NERVE

Case 1. W. H. H., a 19-year-old apprentice seaman, was admitted to the hospital with clinical and laboratory evidence of meningococcic meningitis. He recovered with penicillin therapy. However, during his convalescence, it was noticed that he was very unsteady in his gait and station.

Repeated caloric (cold irrigation of ear canals) and Bárány tests of vertical and horizontal canals failed to yield nystagmus, past pointing, or vertigo. His hearing was only slightly diminished. There was complete bilateral loss of vestibular function in this man.

Opticomotor nystagmus was not tested.

Pharmacologic Tests. Sodium amytal (0.5 gm.) was slowly injected into the arm vein. Within two minutes, definite nystagmus appeared when the patient turned his eyes in any direction except upward. This nystagmus persisted for more

than two hours. During this period the patient was somewhat drowsy.

Case 2. R. D. S., a seaman, second class, aged 19 years, was admitted to the hospital in a comatose state. He had signs of meningeal irritation, and his temperature was 104°F. Laboratory studies established the diagnosis of meningococcic meningitis. He recovered under sulfadiazine and penicillin treatment. When he regained consciousness, he was found to be totally deaf in the left ear and could hear only loud noises in the right. There was spontaneous past pointing with both hands to the right. The gait was broad based and unsteady. There was no spontaneous nystagmus.

Opticomotor Tests. Prompt nystagmus was obtained on confrontation when the striped drum was revolved in the vertical or horizontal planes. All responses were normal.

Caloric Tests. Irrigation of both ears for three minutes with ice-cold water yielded no nystagmus, past pointing, nor vertigo. On one occasion, upon douching of left ear (for stimulation of vertical canals only), a fine transient nystagmus was noted when the eyes were in the extreme right lateral position. This nystagmus varied in intensity from one minute to another.

Bárány Tests. Rotation in clockwise or counterclockwise directions with stimulation of horizontal and vertical canals failed to elicit ocular responses or vertigo. There was absolutely no nystagmus or past pointing. All of these tests showed absence of labyrinthine functions.

Pharmacologic Tests. Sodium amytal (0.5 gm.) was administered intravenously within six minutes. After 0.2 gm. had been injected, the opticomotor nystagmus decreased, and after the administration of 0.3 gm. of the drug, this type of nystagmus could not be demonstrated.

In other words, the opticomotor nystagmus was abolished.* Two minutes after the initial administration of the amytal was made, a coarse nystagmus appeared when the patient turned his eyes to the extreme lateral upward or downward positions. The nystagmus was more apparent to left than to right and more on downward than on upward gaze. However, the nystagmus was found to fluctuate in its amplitude and rate with change in direction of gaze. One minute, the nystagmus was more marked on left lateral gaze; the next minute, it was more apparent on right lateral deviation.

The patient was observed for two hours. During this period, an alternation in the degree of nystagmus was noted, especially when the patient attempted to maintain his gaze in a lateral position. The same was noted when he tried to keep his eyes either in an upward or downward position. When the nystagmus was found to be pronounced in one direction, it was found to be less marked when the eyes were turned in the opposite direction. This periodicity in amplitude and degree of nystagmus was a frequent finding, even in the normal individual.

Comment. In both of these cases (1 and 2), there was evidence of loss of function in the peripheral vestibular apparatus. Meningitis affected both vestibular nerves. Despite the absence of labyrinthine functions, intravenous administration of barbiturate produced nystagmus just as in the normal individual. From these observations, it would appear that the nystagmus produced by barbiturate is not due to irritation of the peripheral portions of the vestibular organ. The effect seems to be central.

* Since the observations on the ocular movements were made with the unaided eye it is not certain whether the opticomotor nystagmus was completely abolished. Small nystagmoid-ocular excursions might have been present during fixation of the rotating drum.

III. PATIENTS WITH LESIONS IN THE BRAIN STEM.

Case 3. J. F., a middle-aged veteran of the first World War, was admitted to the hospital on July 26, 1944, with a history of sudden onset of dizziness, staggering gait, nausea, and vomiting of three weeks' duration. Examination revealed the blood pressure to be 150/100. There was nystagmus on deviation of eyes to the left and paralysis of conjugate gaze upon shifting them to the right. There was also right peripheral facial weakness. The gait was unsteady.

Opticomotor Tests (performed on August 15, 1944). Counterclockwise rotation of the striped drum with its axis in the vertical plane produced slight and slow deviation of the eyes to the right but not much beyond the vertical meridian. There was no nystagmus. In other words, the expected recovery or quick component to the left was not present. Clockwise rotation of the drum elicited prompt nystagmus (with slow deviation of the eyes to the left and pronounced quick component of the nystagmus to the right).

Bárány Tests. Clockwise rotation of the chair immediately produced chin and eye deviation to the left. On cessation of 10 turns (made within 15 seconds), the patient fell to the right. There was marked increase in the nystagmus on left-lateral gaze. This was most apparent in the left eye. Vertigo was present. Counterclockwise rotation of the chair produced no chin nor eye deviation. On cessation of 19 turns, the patient was dizzy, the eyes were deviated to the left, and he was unable to move his eyes toward the midline to the right. There was absolutely no nystagmus, falling, nor past pointing.

Caloric Tests (performed on August 22, 1944). Irrigation of the right ear

with ice water for 20 seconds produced vertigo, past pointing, falling reactions to the right, and an increase in the nystagmus when the patient turned his eyes to the left. Irrigation of the left ear for 180 seconds abolished the spontaneous, preëxisting nystagmus to the left, and yielded slight vertigo, some pallor, and slight past pointing to the right. There was no nystagmus except for minimal jerks with a quick component to the right.

Pharmacologic Tests (performed on August 15, 1944). Sodium amytal (0.3 gm.) was injected intravenously over a period of five minutes. Slight, slow, coarse nystagmus in all directions of gaze was noted after the first two minutes of injection. The nystagmus was most pronounced on left-lateral gaze and was minimal on attempted right-lateral gaze. An additional 0.1 gm. was administered (total 0.4 gm.) and, four minutes later, ocular deviation to the right could be accomplished but not maintained. Although the globes were turned to the right of the vertical meridian, slow movements of the eyes were noted. The movements were to the left (toward the mid position), and it became apparent that the patient was unable to maintain his gaze to the right. On lateral gaze, the nystagmus was rapid and fine, especially marked in the left eye. These ocular phenomena were present for the next 15 minutes of the study.

As in previous cases, opticomotor nystagmus was abolished. Soon after the injection of 0.1 gm. of the drug, the patient declared that his vision was better. He claimed that it was no longer blurred and that the dizziness had disappeared.

Comment. Clinically, this case showed signs characteristic of a lesion in the pons at the level of the facial nucleus. In this patient, barbiturate definitely altered

the ocular movements. Thus conjugate gaze which was prolonged to the right before the injection became apparent after the injection of the drug. The re-appearance of eye movement to the right was associated with a nystagmus to the right. The nystagmus to the left became much more pronounced and more rapid.

Case 4. R. B. F., a young Marine Corps aviator, was admitted to the hospital on August 16, 1944, with a history of acute onset of extreme dizziness, nausea, and vomiting of five days' duration. Examination was negative except for the ocular findings. On direct forward fixation there was fine nystagmus with a quick component to the left. The nystagmus became more conspicuous as the eyes were deviated to the left. Nystagmus was also present on upward and less marked on downward gaze. There was no nystagmus on gaze to the right. The patient complained of marked dizziness when he turned his head and eyes to the left.

Opticomotor Tests (performed on August 19, 1944). Clockwise rotation of the drum with its axis in the vertical plane failed to elicit nystagmus on repeated tests. Counterclockwise rotation of the drum in the vertical position consistently produced prompt nystagmus with a slow component to the right (in the direction of rotation) and a quick (recovery component to the left.* Clockwise or counterclockwise rotation of the drum with its axis in the horizontal plane produced no nystagmus.

Bárány Tests (performed on August 24, 1944). Clockwise rotation of the patient sitting in the Bárány chair produced marked exaggeration of the nystagmus

to the left with vertigo and past pointing. Counterclockwise rotation (8 turns within 10 sec.) yielded a lesser, fine, and more rapid type of nystagmus to the right and only slight past-pointing reaction.

Pharmacologic Tests (performed August 19, 1944). Five-tenths gram of sodium amytal was administered by vein within four minutes. The patient became markedly somnolent and required frequent rousings in order to carry out the study. Nystagmus became evident on gaze to the right and markedly lessened on gaze to the left. Eleven minutes after the final dose was injected, nystagmus was abolished in all directions of gaze and remained absent for two hours during which the tests were performed. Opticomotor nystagmus was similarly abolished and returned three hours after the drug was injected. As the effect of the drug diminished the nystagmus on lateral gaze reappeared. Diplopia on forward fixation at about one meter's distance occurred as an early effect and persisted for about 45 minutes.

Comment. Although there is no conclusive proof that the lesion in this case was in the brain stem, the persistence of the nystagmus on left-lateral gaze for several days and the presence of nystagmus in the vertical plane suggested that the pathologic lesion was central, probably in the brain stem.⁶ Furthermore, the fact that the nystagmus induced by the opticomotor drum was reversed or found to be present only in the direction opposite to that elicited on examination is, according to Brunner,⁷ a sign that the pathologic nystagmus is central and non-labyrinthine. The latter conclusions were confirmed by Scala and Spiegel⁸ in experiments with cats. In this case, barbiturate markedly decreased the pathologic nystagmus (which was present on at-

* These were performed three days after admission, at which time the patient's symptoms had somewhat subsided.

tempted left-lateral gaze) and produced a nystagmus on right-lateral gaze.

IV. PATIENTS WITH LESIONS IN THE CEREBRAL HEMISPHERES.

Case 5. G. B., a 22-year-old Marine, was shot in the right temporal region. X-ray studies revealed a metallic fragment situated deep in the right-temporal lobe near the thalamus. The injury to the right side of the brain produced a left hemiplegia, hemisensory syndrome, and hemianopia. Besides these, the patient had difficulty in ocular fixation. Not infrequently, the head and eyes deviated tonically to the left, especially while he was fixating a target. These, of course, were involuntary and noted on repeated occasions during the entire observation period.

Bárány Tests. Turning tests, clockwise and counterclockwise, yielded essentially normal responses as to nystagmus, past pointing, and vertigo. There was no difference between the ocular reactions on right- and left-lateral gaze. There were no defects in conjugate deviation.

Opticomotor Nystagmus. Clockwise rotation of the striped drum with its axis in the vertical plane produced normal opticomotor nystagmus. Counterclockwise rotation in the same plane also yielded nystagmus, but the quick components to the left were diminished. Rotation of the drum with its axis in the horizontal plane resulted in a nystagmus. This was more pronounced when the drum was rotated in an upward than in a downward direction.

Pharmacologic Tests. Slow intravenous injection of 0.5 gm. of sodium amytal produced the usual barbiturate nystagmus; it was found to be present on vertical or horizontal gaze. There was no apparent inequality between the right and left sides. Moreover, there were no dis-

turbances in conjugate gaze to either side. The patient was able to maintain his gaze to the left just as well as to the right. Opticomotor nystagmus was not found with rotations of the striped drum in any direction.

Comment. In a patient, with a lesion in the right cerebral hemisphere, who showed difficulty in ocular fixation, intravenous injection of sodium amytal produced: (a) the usual barbiturate nystagmus, (b) no disturbances in ocular gaze, (c) no difference between the right and left sides, and (d) abolition of opticomotor nystagmus just as in the normal individual. In other patients with disturbances in ocular fixation due to a lesion in the right frontoparieto-occipital regions, intravenous barbiturate failed to reveal changes that were significantly different from those found in the normal.

Thus it appears that barbiturate does not materially influence the ocular defects caused by lesions in the cerebral hemisphere. The responses are the same as in the normal, and this is in contrast to the findings in cases of brain-stem lesions. From the available data thus far cited, it would seem that: (a) nystagmus produced by barbiturate is not due to irritation of semicircular canals, as demonstrated by cases 1 and 2; (b) barbiturate influences ocular responses in patients with lesions of the brain stem, as demonstrated by the reversal of direction of nystagmus, by the abolition of the pathologic unilateral nystagmus, and by the provocation of nystagmus to the normal side; (c) barbiturate has no apparent effect on eye movements in patients with lesions in the cerebral hemisphere; and (d) barbiturate abolishes the opticomotor nystagmus normally elicited with the striped drum. Evidently the action of the drug is manifested either by the production of a nystagmus (apparent when the eyes are held approximately in mid posi-

tion, or by the abolition of nystagmus (with the eyes fixating in the mid position). The latter was also observed in cases of latent nystagmus.*

V. PATIENTS WITH VARIOUS FORMS OF NYSTAGMUS:

A. Latent Nystagmus.

Case 6. A. P. W., an 18-year-old seaman, second class, had been aware of difficulty of vision since the age of six years. He had noted that whenever he closed one eye, objects within his gaze quivered and moved back and forth in a horizontal plane (oscillopsia). This subjective impairment was more marked in the right eye than in the left. There was no such oscillopsia with both eyes open.

Examination revealed a divergent squint and paralysis of convergence. Visual acuity was diminished when each eye was tested separately, in the right eye more than in the left; binocular vision was much better. On covering either eye, a marked nystagmus was noted in the uncovered as well as the covered eye. The same type of nystagmus was obtained by splitting the binocular vision. This was accomplished by holding a cardboard between the two eyes in the sagittal plane. There was no spontaneous nystagmus on binocular fixation in any direction.

Opticomotor Tests. Direct confrontation with the revolving, striped drum in the vertical or horizontal position did not produce nystagmus. However, a slight nystagmus was obtained when the drum was in the vertical position but held a little to the right or left of the midline.

Barány Tests. Marked coarse nystagmus was produced by the usual rotation

of the chair in clockwise and counterclockwise directions. However, there was minimal past pointing and no subjective vertigo.

PHARMACOLOGIC TESTS. Sodium amytal administered intravenously elicited the following results. A total of 0.35 gm. of the drug was delivered in divided doses in three minutes. At the end of this period, nystagmus was observed on right- and left-lateral gaze. The latent nystagmus previously found on uniocular fixation was no longer present and remained absent for the next 25 minutes. Visual acuity on uniocular fixation was much improved. Opticomotor nystagmus could not be obtained with eyes held in mid position.

The patient was observed for 90 minutes. During this period, it was found that the nystagmus, on horizontal gaze, presumably induced by the drug, varied in speed and amplitude from side to side. At one moment, it was more pronounced to the right, at another to the left side, with reversal occurring approximately at one-minute intervals. It was also noted that, as recovery from the barbiturate became generally manifest, the latent nystagmus reappeared.

Comment. The barbiturate in this patient abolished a nystagmus (latent nystagmus). Observation in 12 other cases of so-called congenital nystagmus revealed the same results in all but two. The abolition of nystagmus was invariably accompanied by a subjective and objective improvement in visual acuity. Such improvement has been noted in many patients with such nystagmus and one of these cases was described in detail elsewhere.⁸

B. Voluntary Nystagmus.

Case 7. A. R. G., a Marine, aged 25 years, was admitted to the hospital for investigation of recurrent attacks of un-

* Latent nystagmus can be demonstrated by covering one eye or by splitting binocular vision by holding a piece of paper close to the bridge of the nose in the sagittal plane. The nystagmus elicited only with monocular vision is apparent even when the eyes are in the mid position.

consciousness with accompanying paralysis of the right arm and leg. These were ultimately found to be psychogenic. Physical examination was remarkable only in the presence of fine, rapid, horizontal nystagmus to either side, which the patient claimed was voluntary. He was able to demonstrate the nystagmus quite at will. The nystagmus was more of a tremor of the eyes, rather than the to-and-fro lateral movements. There were no quick and slow components. He stated that he had been aware of a spontaneous "shaking" of his eyes, six years before he entered the service. He also claimed that, during his production of the nystagmus, objects widened in the horizontal but not in the vertical plane. Apparently he learned to bring this about by his own volition and to stop it in the same fashion.

Opticomotor tests were not performed.

Bárány Tests. Clockwise rotation of the chair yielded nystagmus to the left; counterclockwise turning yielded nystagmus to the right. The responses were slight and of brief (3- to 5-sec.) duration. There was minimal vertigo and past pointing. Vigorous and prolonged turning did not exaggerate the results. Interestingly enough, the patient was able to alter this induced nystagmus at will. It was manifested by an increase in the degree of eye movements (nystagmus) elicited by the turning chair. He could superimpose his voluntary nystagmus upon the nystagmus produced by the Bárány turning tests.

Pharmacologic Tests: Sodium amytal (0.5 gm.) was administered intravenously in about five minutes. At the end of four minutes, slight coarse nystagmus was present in the horizontal gaze. There was little or no nystagmus on upward gaze. The patient was somewhat drowsy for 20 minutes. Voluntary nystagmus was attempted but failed. This time he had no "control of the eyes." Strong

effort to produce voluntary nystagmus resulted only in an upward rolling of the eyeballs. The inability to produce nystagmus at will lasted 40 minutes. Finger-to-nose tests showed no ataxia. There were no gait disturbances and the station was secure.

Comment. Here is another example of the abolition of a form of nystagmus (voluntary). Although this patient did not have clinically demonstrable signs of a lesion, he did seem to show a decreased or minimal reaction to vestibular stimulation. The most remarkable feature in this case was the voluntary production of nystagmus and its abolition with barbiturate.

C. Postural Nystagmus.

Case 8. R. M. S., a steward's mate, second class, aged 19 years, complained of motion sickness. He had been troubled for as long as he could remember with nausea and vomiting when riding in vehicles. He had never been able to lie flat upon his back without a feeling of marked dizziness, but had always slept with his head supported by a pillow. General examination was negative except for the fact that sudden retraction of the patient's head produced fine and very rapid vertical nystagmus and extreme vertigo.

Opticomotor Tests. Prompt, normal responses were obtained with rotation of the striped drum in any plane.

Bárány Tests. With only three turns of the revolving chair in either direction, severe vertigo and nausea ensued with accompanying rapid, coarse nystagmus, past pointing, and falling reactions of typical type. The nystagmus thus induced lasted well over 15 seconds.

Pharmacologic Tests. Intravenous sodium amytal (approximately 0.4 gm.) was administered within six minutes. Typical barbiturate nystagmus appeared

after 0.1 gm. of the drug had been injected. Opticomotor nystagmus was promptly abolished. The most remarkable effect of the barbiturate was the abolition of nystagmus elicited on retraction of the head. Not only did this nystagmus disappear but the dizziness previously experienced by the patient on this maneuver was also no longer present. When the effect of the drug had worn off, retraction of the head again produced the vertical nystagmus and severe dizziness.

Comment. The cause of the postural nystagmus in this case could not be ascertained. The fact that the nystagmus was manifest only in the vertical plane suggested that the pathologic lesion was in the brain stem.⁵ However, Spiegel and Scala⁹ were able to produce vertical nystagmus by lesions in the labyrinth. Hence, a peripheral origin could not be excluded. Be that as it may, the most significant finding in this case was the abolition of postural nystagmus by intravenous injection of sodium amytal. Thus far it is apparent that barbiturates influence eye movements either by production or by an abolition of nystagmus. With these facts in mind, we studied the effect of barbiturate in a patient who showed impairment of ocular movements, apparently due to hysteria.

VI. PATIENTS WITH OCULAR PALSIES

Case 9. J. D. G., a 41-year-old Marine, was admitted to the hospital complaining of weakness, fatigue, nervousness, difficulty in walking, twitching of both hands, apparent lapses of consciousness, and sudden spells of unexplained rapid heart action with breathlessness and feelings of apprehension.

Examination revealed staring facies and bizarre gait with alternate dragging of lower limbs. There were numerous bizarre types of twitchings and tremors of hand and feet, and peculiar ataxia of

all point-to-point tests. The eye examination showed spasms of convergence and apparent weakness of both external rectus muscles. Lateral eye movements were almost absent. On attempted upward gaze, the eyes rolled upward, exposing the inferior scleras but the upper lids failed to retract. In fact, they partly closed, thus giving a picture similar to Bell's phenomenon. There was no true weakness of the facial muscles. There were inconstant, atypical areas of sensory deficit of hemi-corporal distribution alternating with glove and stocking type of anesthesia. The patient's emotional attitude was one of *belle* indifference. The clinical picture was one of hysteria. This was confirmed, by the history and by subsequent special personality studies.

Pharmacologic Tests: Following intravenous injection of 0.5 gm. of sodium amytal, nystagmus appeared when the patient attempted to direct his eyes away from the mid position. Following the appearance of this nystagmus, his eye movements improved. The apparent weakness of the external recti disappeared. Conjugate eye movements were now good in all directions and associated with barbiturate nystagmus. Upward gaze was prompt and accompanied by normal, concomitant retraction of the superior eyelids. Following this procedure, the patient was able to move his eyes in a normal fashion during the remainder of his hospitalization period.

Comment. Here, again, barbiturate altered eye movements. It is not surprising that sodium amytal abolished hysterical paralysis of ocular muscles—this has been noted by many observers. However, one is not always certain whether the hysterical ocular-muscle palsy is on a conscious or unconscious level. It is possible that the amytal specifically altered ocular function in this case just as it did in the case of voluntary nystagmus. In other words,

the ability to control eye movements was abolished by the amytal. This does not necessarily mean that hysterical ocular paralysis is entirely on a voluntary basis, for we have pointed out that ocular disorders due to organic disease are also influenced by barbiturates. The following case raised the question whether suppression of an ocular movement was on a voluntary or involuntary basis.

Case 10. J. C., a 34-year-old steward's mate second class, was admitted to the hospital for study of an internal squint of the right eye which, he claimed, had occurred about three months before admission.

Preënlisment history disclosed poor school and employment records, repeated arrests for alcoholism, and other signs of defective social adjustment. He had always been impulsive and emotionally unstable. Psychometric tests revealed moron or borderline intelligence level.

Examination was essentially negative except for an internal strabismus of the right eye of about 40°. This strabismus seemed to vary in degree. The patient also claimed he could not turn either of his eyes to the right or left. On several occasions, however, it was reported that the patient's eyes were perfectly straight. This was apparent when he was intoxicated with alcohol. During that period, his eyes were not only straight but moved coördinately in all directions. All eye movements appeared normal at this time. This suggested to some observers that the patient was simulating his ocular disorder.

Bárány Tests. These failed to produce significant nystagmus on clockwise or counterclockwise turning. The absence of nystagmus may have been related to his claim that he could not move his eyes to either side (suppression of eye movements?). The usual vertigo, past-point-

ing, and falling reactions were present. The lack of oculomotor reaction suggested a dysfunction in the vestibular system. However, this was not conclusive. In order to exclude the conscious element or that of malingering (conscious suppression of eye movements), the patient was subjected to special tests.

(1). The patient was stimulated with the electric-shock machine, and a grand-mal seizure was produced. During and immediately following the convulsion, the internal squint disappeared and conjugate eye movements were found to be present. Five minutes after the convulsion, the strabismus returned, also the impairment of horizontal eye movements. At this time and during the next 35 minutes, the patient was amnesic, confused, and totally disoriented. It was assumed that, during this altered mental state, the patient was not conscious of intent to deceive. It is doubtful whether he could simulate the strabismus which returned during this period. And (2), petit-mal seizures, also electrically induced, failed to change the squint although the patient was rendered confused and amnesic. Again, the patient's mental state precluded simulation, and these findings confirmed the observations made following grand-mal seizures. The squint was not due to malingering.

Pharmacologic Tests. Slow injection of 0.5 gm. of sodium amytal into the arm vein produced, within a few minutes, a change in the ocular status. The internal squint disappeared, and the eyes appeared to be normal. There was no nystagmus during this period of observation. Conjugate, horizontal eye movements were executed on direct command, on follow fixation, and on fixation with passive turning of the head. There was no difference between right and left side.

While under the influence of the barbiturate, the patient spontaneously volun-

teered that he had been subject to ocular disturbances for a number of years before enlistment. He had double vision, the right eye turned inward, and the lids squinted. These were particularly apparent when he was "nervous" or emotionally tense.

The pharmacologic study was repeated at a later date, when pentothal sodium (0.1 gm.) was given by intravenous injection. Within one minute, the internal strabismus disappeared. There was no nystagmus. A very transient nystagmus on lateral gaze appeared on the administration of an additional 0.1 gm. of the drug. Again the ocular squint disappeared.

Comment. Barbiturate abolished an ocular squint. The same effects were apparently obtained when the patient was intoxicated with alcohol. The fact that the squint persisted during the period of postconvulsive confusion and during the amnesia produced by an electrically induced petit-mal state, would seem to exclude the possibility of malingering or of voluntary ocular deviation with intent to simulate an illness. If the squint were due to hysteria, it must have been on a subconscious basis. The absence of nystagmus during the period of barbiturate intoxication and on Bárány turning tests suggests an organic disorder in the central vestibular system and not a suppression of eye movements. According to Bartels,¹⁰ lesions or disorder of the central vestibular system may produce ocular squint.

It is improbable that the ocular squint was abolished by action of barbiturate on the ocular muscles. In patients with ocular-muscle palsies, intravenous injections of sodium amytal did not alter the paralysis due to a lesion in the abducens nerve nor did it influence ocular movements in a patient with congenital weakness of all the external ocular muscles.

DISCUSSION

From the foregoing observations, it is apparent that the barbiturates influence eye movements which involve a cortical component (voluntary deviation and fixation). Although the available clinical data cannot explain the *modus operandi* of this effect, they suggest that the site of action of this drug is in the cerebral cortex and partly in the brain stem. Analysis of the case material will show that the most conspicuous alterations in eye movements were noted in patients with disease of the brain stem. However, it is realized that the evidence is not altogether conclusive because the drug probably acts at all levels of the nervous system.

According to Goodman,¹¹ barbiturate in small doses produces its effect largely by release "phenomena and consequent overactivity in the nervous system, especially in subcortical and lower regions." Release of cortical inhibitory influences on the central vestibular system might thus explain the patient's inability to maintain gaze in any one direction when under the influence of a barbiturate. The inability to maintain voluntary gaze is manifested largely in the form of nystagmoid movements yielding the clinical picture of barbiturate nystagmus. Since voluntary nystagmus and opticomotor nystagmus each involves a cortical component, the same theory may explain abolition of such nystagmus.

This theory, however, does not account for the abolition of positional or other forms of nystagmus cited in the text. Nor does it entirely explain the transitory disappearance of an ocular squint. An additional hypothesis would be that barbiturate, a well-known brain anesthetic,^{3, 12} also interferes with impulses going to and coming from the vestibular nuclei. Since the latter have a strong influence on the ocular status,¹³

any alteration in the function of these nuclei will be reflected by a change in eye movements.

Whatever the explanation may be, it is clinically significant that barbiturate abolishes various forms of nystagmus and alters eye movements which involve a cortical component.

SUMMARY

1. Intravenous injections of barbiturate (sodium amytal 0.5 gm.) produces in the normal individual: (a) coarse nystagmus and inability to maintain gaze on voluntary deviation of the eyes in any one direction, and (b) abolition of opticomotor nystagmus as elicited by rotation of a striped drum upon which the patient fixates.

2. Intravenous injection of barbiturate also alters or decreases the nystagmus due to disease of the brain stem and abolishes such types of nystagmus as:

(a) latent (nystagmus obtained with monocular fixation or on exposure to darkness), (b) positional (nystagmus obtained on retraction of the head), (c) voluntary (nystagmus obtained by the patient at will), and (d) various forms of so-called congenital nystagmus.

3. Intravenous injection of barbiturate restored eye movements in patients with hysterical ocular palsies and temporarily corrected an ocular squint of unknown origin.

4. It is suggested that barbiturate in mild doses interferes with ability to control eye movements and ocular fixation by its action on the cerebral cortex, brain stem, and intermediate neuronal structures. Eye movements which do not necessarily involve a cortical component might be altered by barbiturate as a result of its action on the brain stem.

THE PATHOLOGIC CHANGES IN RABBIT EYES RESULTING FROM EXPOSURE TO LIQUID NITROGEN MUSTARDS*

WILLIAM O. LAMOTTE, JR., M.D., AND IRVING H. LEOPOLD, M.D.
Philadelphia

Two vesicant agents of potential use in chemical warfare have been designated HN_2 (dichlor-diethyl ethylamine) and HN_3 (trichlor-triethylamine), both known as nitrogen mustards. In order to determine the effect of these agents on ocular structures, rabbit eyes were exposed to varying amounts of each until a standard clinical ocular lesion was established for each agent. A series of such standard lesions was produced for each agent, and the following pathologic studies carried out to determine the type of histologic change present.^{1, 2}

The eyes of young chinchilla rabbits were burned on the superior limbus by a standard amount of liquid vesicant agent delivered through a microsyringe.³ The dose of HN_2 was 0.8 mg. in one series, and this dose was reduced to 0.4 mg. in another series in order to produce a milder lesion. The dose of HN_3 was 0.4 mg. in all instances. The HN_2 eyes were enucleated at 1 hour, 6 hours, 12 hours, 24 hours, 2 days, 3 days, 5 days, 8 days, 12 days, and 3 weeks following burning with the vesicant. The HN_3 eyes were similarly removed at intervals of 2½ hours, 6½ hours, 24 hours, 2 days, 4 days, 5 days, 10 days, 14 days, 33 days, and 16 months. The discussion of pathologic changes concerns average eyes studied at each time interval.

All eyes were fixed in formalin for a minimum of 24 hours, following which

they were prepared for histologic section by the celloidin technique. The sections were cut 16 μ . thick and stained with hemotoxylin-eosin. Photographs were taken to show typical changes at the various stages of the lesions. Detailed protocols of each stage were outlined in the original work, but here a general summary of the pathologic changes will be given.

HN_2 EYES

The conjunctiva is the site of edema and congestion, followed progressively by increasing cellular infiltration, loss of epithelium, necrosis, and degeneration, a process which never reverses in the more severe 0.8 mg. lesion. At the end of three weeks, the conjunctiva in the 0.4 mg. lesion remains edematous, thickened, congested, and infiltrated, with inflammatory cells, but has not undergone necrosis. The corneal epithelium shows slight edema of the basal cells as early as one hour (fig. 1) which gradually increases in severity (fig. 2) so that by 12 hours (fig. 4) the cells are beginning to separate from the underlying stroma, and by 24 hours have largely become lost (fig. 6). Complete denudation persists with attempts at regeneration of epithelium beginning around the third day, such efforts being accompanied by edema of the new cells and repeated loss (fig. 11). The regenerative attempts appear even after the eye has perforated. But at three weeks, complete repair has not even occurred in the milder 0.4 mg. lesion, epithelium being found only over about half the corneal section.

Slight edema at one hour is also the first change observed in the corneal

stroma (fig. 1). This increases slightly during the first six hours (fig. 2), during which time the stromal cells first begin to show very early pyknotic changes and the corneal fibers give evidence of poor staining properties. Yet the stromal changes remain relatively mild until the period from 12 to 24 hours, when the edema becomes marked enough to increase the corneal thickness and the stromal cell damage is sufficient to result in a decrease in the number present (fig. 6). The stage of infiltration with inflammatory cells begins between 24 and 48 hours; in some cases, the infiltration is marked by 48 hours, in

Fig. 12 (LaMotte and Leopold). Further necrosis and increased cellular infiltration of iris. 5 days.

gone and the stromal fibers have become hyalinized and structureless. It is at about the 48-hour stage that small vessels are first seen in the corneal substance near the limbus. In the 0.8 mg. lesion, vascularization beyond this point seems to be inhibited for, although the vessels can be found near the limbus throughout the course of the lesion, they never extend far toward the center of the cornea. In the 0.4 mg. lesion, on the other hand, vascularization is a prominent feature, and by three weeks vessels are still seen in all layers and in some cases, extend almost to the center of the cornea. In the 0.8 mg. lesion, loss of corneal substance through

slough begins as early as 48 hours and increases rapidly so that some eyes perforate by the end of the first week, although most remain intact until the middle of the second week. No successful repair being accomplished, the eyes appear, at the

Fig. 13 (LaMotte and Leopold). Corneal slough in eye which has perforated. Necrosis and hyalinization of iris and ciliary processes. 8 days.

Fig. 14 (LaMotte and Leopold). Intact area of a perforated cornea showing regenerated epithelium overlying necrotic and hyalinized stroma. 12 days.

end of three weeks, as necrotic degenerated masses. After three weeks, the milder lesion presents an intact, but thickened, edematous, infiltrated, and vascularized stroma, with no stromal cells in evidence.

The most striking and most severe changes occur in the iris and ciliary body. By the end of six hours (fig. 3), edema and congestion are much more marked here than in the cornea, and by 12 hours (fig. 5), engorgement has become tremendous. At this time there is already evident slight damage to the endothelial cells of the uveal vessels, and some free hemorrhage into the edematous iris stroma. Likewise, protein material is seen by this time in the anterior chamber.

Fig. 15 (LaMotte and Leopold). Further necrosis of ciliary processes, iris, and cornea. 12 days.

Fig. 16 (LaMotte and Leopold). Iris and cornea. No significant alteration in normal structure. 2½ hrs.

Fig. 17 (LaMotte and Leopold). Cornea. No significant change. 6½ hrs.

Fig. 18 (LaMotte and Leopold). Iris. No significant alteration from normal. 6½ hrs.

Necrosis of the iris becomes evident between 12 and 24 hours and, by 48 hours (fig. 9), has proceeded rapidly to the point where normal cellular structure is completely lost. The general architecture is barely recognizable because of the advancing hyaline degeneration, and the edematous, necrotic structure shows invasion by polymorphonuclear leukocytes and macrophages. This process continues unabated in the 0.8 mg. lesion so that by the end of three weeks the iris and ciliary body are but a scarcely recognizable part of the necrotic eye. Even in the three-week-old 0.4 mg. lesion, the process has been severe enough so that the anterior uveal structures have become hyalinized, rendered relatively avascular by the de-

struction of the endothelium of the blood vessels, necrotic and functionally useless in appearance. Yet reparative processes, absent in the 0.8 mg. lesion, are seen in the presence of well-formed fibroblastic bands forming anterior synechiae and occlusio pupillae.

Posterior segment changes are absent except for the expected events in an endophthalmitis accompanying the more advanced and severe stages of the lesions just described.

Fig. 32 (LaMotte and Leopold). Regenerating epithelium, edema of superficial stroma, vascularization and cellular infiltration (small round cells and polymorphonuclear cells) chiefly in mid-stromal zone. Intact Descemet's and endothelium. 33 days.

Fig. 33 (LaMotte and Leopold). Intact cornea of normal thickness with no infiltration, vascularization or alteration in normal corneal histology. 16 mos.

HN₃ EYES

The conjunctiva following exposure to HN₃ liquid burns shows, histologically, edema and mild inflammatory cell infiltrations. This change is first noted by 2½ hours after exposure, and the entire process is gone by one month, leaving practically no permanent damage. The limbal region reveals signs of moderate congestion, and inflammatory cell infiltration is also present by 2½ hours, increasing in amount for the first 10 days. The inflammatory cells at first are eosinophilic-staining polymorphonuclear cells, but by the 14th day small round cells are also pres-

Fig. 34 (LaMotte and Leopold). Same cornea as figure 33 at site of only histologic evidence of damage, showing superficial vessels. 16 mos.

ent. The limbal changes disappear completely after one month.

There is very little evidence of corneal change before 24 hours, at which time areas of epithelium (fig. 19) have been lost, although the basal cells are not at first included. Later, however, complete denudation may occur. Edema of the corneal stroma and death of some of the stromal cells also begin by 24 hours. By 48 hours, these changes have increased, and polymorphonuclear cell infiltration of the stroma has begun. By the fourth day, the greatest degeneration of stromal substance is present superficially (fig. 23). The corneal endothelium remains intact except for local cell swelling until the fifth day, when small areas are lost. At this time, the epithelium has begun to regenerate. Vessels have invaded the stroma by the 10th day, lying chiefly in the mid-stromal zone, although a few are superficially situated. Repair of the stroma by young fibroblasts is also under way by the 10th day, and by the end of two weeks the endothelium is again intact. Vessels and cellular infiltration are still present after one month (fig. 32), and occasional bullae may be found at this time. After about a year, the cornea has largely recovered except for areas of superficial stromal vascularization (fig. 34).

The only change noted in the iris is mild edema starting about two days after exposure. Very little congestion or cellular invasion of the iris ever appear. The anterior chamber shows only a mild exudate around the second day which disappears without sequellae by the 10th day (figs. 18, 24, 29).

DISCUSSION

Liquid HN_2 produces severe ocular damage, an 0.8 mg. lesion resulting in a perforated and lost eye. The milder dose of 0.4 mg. produces severe necrosis of the cornea, but does not prevent reparative

processes from gaining a foothold. Yet at three weeks, the extent of the vascularization appears to be defeating its purpose and instead contributes to the loss of function of this tissue. It is quite evident that HN_3 produces definite corneal changes but, in most instances, the damage is not irreparable. The vascularization here is chiefly of the deep type, and most of these vessels may disappear. The superficial vascularization noted after one year may be related to the bullae previously present. The chief difference between the action of the two vesicant agents is in the changes which they produce in the iris and the ciliary body. Whereas, in HN_3 burns the process never goes beyond the stage of edema, mild congestion, and very slight cellular infiltration, with subsequent complete return to normal histology, the process in HN_2 burns is one of severe necrosis of anterior uveal tissue, degeneration, and loss of function to the extent that any return to normal appears impossible.

The work of Scholz⁴ on the pathology of HN_2 lesions resulted in essentially the same conclusions, although the material studied was obtained from less severe lesions produced, in most instances, by vapor rather than liquid vesicant agents. Maumenee⁵ compared the histopathology of the ocular lesions produced by these two nitrogen mustards and, in addition, a third nitrogen mustard known as HN_1 , together with mustard itself, and concluded that all the lesions were so similar that it was impossible to differentiate one from the other histologically except for the depth of the damage done; the damage to the deeper tissues being greatest with HN_2 , intermediate with HN_3 , and least with HN_1 and mustard.

SUMMARY

1. The histopathologic changes in the rabbit eye due to liquid preparations of the

nitrogen mustards HN_2 and HN_3 are presented and compared.

2. The changes resulting from HN_3 are relatively mild and, in the dosage used, do not preclude recovery.

3. The changes resulting from HN_2 are severe and frequently result in the

complete destruction of the eye.

4. The same major histologic events occur in lesions produced by both of these vesicant agents, the chief difference resting in the degree of damage occurring in the anterior uveal structures.

EFFECT OF OILY DROPS ON EYES EXPOSED TO MUSTARD VAPOR*

GEORGE I. UHDE, M.D.

Portland, Oregon

AND

E. B. DUNPHY, M.D.

Boston, Massachusetts

During the recent war, it was frequently stated that oily drops should never be used in an eye which might be exposed to mustard vapor. The reason given was that mustard, being soluble in fat might concentrate in the oily drops resulting in a serious eye burn. That this did not seem probable to us was shown by the fact that, experimentally, a paraffin-liquid mustard droplet caused a milder lesion on a rabbit's cornea than a pure mustard droplet of equal strength. Furthermore, Sollman,¹ in 1919, had shown that certain oily substances, such as linseed oil and cod-liver oil, had a definite prophylactic effect against mustard on the skin.

The following experiments were undertaken to ascertain the truth of the matter and, now that security regulations have been lifted, it was thought advisable to put our conclusions on record.

EXPERIMENTS ON RABBITS METHODS AND RESULTS

EXPERIMENT 1

Two drops of Radiostol (irradiated ergosterol, British Drug Houses), which has a peanut-oil base, were instilled into the right eyes of six rabbits immediately prior to, and at the mid-point of, an exposure to 4 mg./m³ of mustard vapor for 3½ hrs. (Ct† 840). The left eyes were left untreated as normal controls.

* The authors completed this work while attached unassigned as experimental officers in ophthalmology to the Physiology Section (A. Fairley, head), Chemical Defence Experimental Station, Porton, England.

† Ct is a term used in chemical-warfare language to express unit dosage. Ct equals concentration of any gas times period of exposure in minutes.

Fig. 1 (Uhde and Dunphy). Both eyes were exposed simultaneously to 4 mg./m^2 of mustard vapor for $3\frac{1}{2}$ hours (Ct 840). Two drops of vitamin D in peanut oil were instilled into the right eye just prior to and at the midpoint of exposure. The left eye was an untreated control. This photograph was made at 72 hours.

The lids of both eyes were sutured open to prevent blinking. The eyes were examined by slitlamp at stated intervals thereafter.

There was a significant difference between the two sets of eyes even as early as 24 hours, the treated eyes showing much less irritation. By the third day, the treated eyes were quite normal; whereas, the untreated control eyes were not only congested, but also showed considerable corneal edema (fig. 1). By the 36th day, the corneas of three of the six untreated control eyes were scarred and vascularized.

EXPERIMENT 2

Under the same conditions as experiment 1, the right eyes of six rabbits were prophylactically treated with vitamin A in peanut oil.

At the end of 24 hours, the treated eyes were better in four rabbits (67 percent), and the same as the control eyes in two rabbits (33 percent). By the 36th day, three of the rabbits were dead, but the corneas of the remaining three un-

treated control eyes, were scarred and vascularized, while only one of the three treated eyes showed any abnormality—a slight nebular scarring.

EXPERIMENT 3

The right eyes of six rabbits were treated as in experiment 1, but with cod-liver oil. The exposure was increased to a dosage of (Ct 1,950).

At observation periods of 24 hours, 9 days, and 19 days, the treated eyes were consistently better than the untreated eyes in four rabbits (67 percent), and equal in two rabbits (33 percent). Two of the untreated eyes developed corneal vascularization by the 19th day.

EXPERIMENT 4

Forty-two rabbits were treated with various oily solutions as shown in the following table, and in the same manner as in experiment 1, but were exposed to an even higher dosage (Ct 2,520). In this case, although all eyes showed damage, the ones treated prophylactically with vitamin D in peanut oil were much less

severely affected than their untreated controls. Olive oil, liquid paraffin, and linseed oil all appeared to afford some measure of protection, also.

EXPERIMENT 5

Since vitamin D in peanut oil appeared to be the most effective of the various oily drops in protecting the cornea, the following experiment was done. The

7,400). The left eyes were untreated.

At 24 hours, 48 hours, and 35 days there was very little, if any, difference between the treated and untreated eyes, all eyes being severely damaged.

EXPERIMENTS ON HUMAN EYES

EXPERIMENT 6

Six volunteers with normal, healthy eyes were exposed to mustard vapor of

right eyes of two rabbits were treated with three drops of Radiostol just before exposure to a very heavy dosage (Ct 7,400). The left eyes were untreated. A specially designed type of respirator was worn to protect the breathing passages, but which left the eyes exposed. Special eye specula were used to prevent blinking.

At 24 and 48 hours there was very little difference between the treated and the untreated eyes. At 35 days the corneas of all eyes were severely scarred and vascularized.

The right eyes of two other rabbits were treated with three drops of Radiostol just after exposure to a dosage (Ct

an approximate dosage (Ct 90). All wore industrial-type respirators which protected the respiratory tract, but left the eyes exposed. Just before entering the gas chamber, each volunteer received two drops of either vitamin A in peanut oil or Radiostol in the right eye only, the left eye remaining as the control. All the volunteers eventually developed a mild chemical ophthalmia in both eyes characterized by conjunctival injection, grayish flecks in the corneal epithelium, photophobia, and lacrimation.

Daily examinations were made. The results are shown in table 2. While these two oils appear to have given slight protection to some of these human eyes ex-

posed to a dosage (Ct 90), the results cannot be called significant as was the case in the rabbits exposed to a dosage (Ct 840). However, it is certain they did not have a deleterious effect, as frequently predicted.

EXPERIMENT 7

Under the same conditions as those of experiment 6, another group of six volunteers was exposed to an approximate dosage (Ct 90). However, prophylactic treatment was not given this group, but instead, upon emerging from the gas chamber, each man had two drops of either vitamin A in peanut oil or Radiostol instilled into the right eye, the left eye remaining untreated as the control. The right eyes were treated with these oils three times daily for the next four days. The treated and untreated eyes were compared at various intervals to see if any difference could be noted. All the men developed mild chemical ophthalmia as in experiment 6.

Results are shown in table 3. There were no essential differences between the treated and untreated eyes.

CONCLUSIONS

One eye of each of 64 rabbits was treated with various oily drops just prior to and during exposure to mustard vapor, dosages (Ct) varying between 840 and 7,400. The opposite eye was untreated and

used as a control. It was found that the lesions of the treated eyes were less severe in 40 rabbits (62.5 percent), equal in 23 rabbits (36 percent), and more severe in one rabbit (1.5 percent). When the dosage (Ct) was 840, complete protection in the treated eyes was obtained with Radiostol (peanut-oil base). Even with dosages (Ct) as high as 2,520 most of the oily drops used appeared to give a certain degree of protection to the cornea. When the dosage (Ct) was very high (7,400), there was very little, if any, difference between the treated and the untreated eye, all being severely damaged.

Twelve human volunteers were exposed to mustard vapor, dosage (Ct 90). One eye of each volunteer was treated with oily drops either before or immediately after exposure, the opposite eye serving as a control. Vitamin A, in peanut oil, or Radiostol instilled into six eyes before exposure did not significantly influence the degree of the lesion produced. Vitamin A, in peanut oil, or Radiostol instilled into six eyes three times daily for four days following exposure did not appear to delay normal recovery.

It seems obvious from these experiments that the current belief in the danger of using oily drops in the treatment of eyes exposed to mustard-gas vapor is unfounded.

SEED GRAFTING OF THE CONJUNCTIVA IN THE TREATMENT OF SYMBLEPHARON

A. HAGEDOORN, M.D.
Amsterdam, Holland

In November, 1928, the right eye of F. G. was severely damaged by an accident in which molten iron entered the conjunctival sac. Treatment could not prevent severe scarring of the cornea, complete symblepharon of the inferior eyelid, and other cicatrices in the superior cul-de-sac (fig. 1). On February 2, 1929, and on February 1 and April 4, 1930, plastic operations were performed elsewhere, but

by Braun and Wagenstein and developed by J. Staige Davis. The latter "uses a straight intestinal needle held firmly in a straight-nose hemostat and, after the point of the needle is introduced into the epidermis, it is raised, producing a small cone of skin. The base of the cone is cut through with the down-turned blade of a sharp knife. The grafts are somewhat universally, although erroneously, called

the result was poor, and on September 27, 1930, a total blepharorrhaphy was done.

When I saw the patient, he believed the right eye to be blind but complained of the cosmetic aspect of the blepharorrhaphy. The ordinary procedures did not seem advisable, the less since they had proved a failure in this case in the hands of an experienced ophthalmic surgeon.

Thin Ollier Thiersch dermo-epidermic grafts, with their whitish discharge give poor results; and, although I have had good results in some cases, mucous-membrane transplants are by no means ideal (Hughes¹). In studying this case, I came on an interesting technique described by Horsley.²

The pinch graft is a procedure devised

by Braun and Wagenstein and developed by J. Staige Davis. The latter "uses a straight intestinal needle held firmly in a straight-nose hemostat and, after the point of the needle is introduced into the epidermis, it is raised, producing a small cone of skin. The base of the cone is cut through with the down-turned blade of a sharp knife. The grafts are somewhat universally, although erroneously, called pinch grafts, since they are originally cut by pinching a cone of skin with tissue forceps and cutting off the base with scissors. This particular technique should be abandoned since the tissue forceps and the scissors produce too much trauma." Since the name "pinch graft" is in contradiction to the major rule of plastic surgery that a transplant should be handled as delicately as possible, the conjunctival variety of the procedure was called "seed grafting."

OPERATION

The patient was operated on on April 22, 1941. The palpebral fissure was reopened. The inferior part of the cornea was found to be leukomatous and covered by connective tissue, although free from

the eyelids. The superior part was clear; the pupil very narrow with *seclusio pupillae*. The patient proved to have definite perception of light; even the direction from which the light came was recognized. There was, consequently, no indication for enucleation.

The symblepharon of the inferior eyelid with the sclera began at about the region of the limbus corneae and was complete, extending from the outer to the inner canthus. The margin and body of the lid for its entire length were inseparably attached to the scleral wall of the eye.

It proved somewhat difficult to free both structures, and a pigmented area was found on the bulbus at the site of a perforation from a former operation. After the inferior eyelid had become freed of the eyeball, it proved to be of about normal thickness, so that no connective tissue had to be resected. The tissues were divided beyond the region of the inferior cul-de-sac down to the inferior bony margin of the orbit in view of the unavoidable postoperative shrinkage.

The superior cul-de-sac was inaccessible because of some bands of connective tissue separated by crypts. The situation now revealed itself to be far worse than could be inferred from the case history of 1930.

The bands were cut or resected, and a new superior cul-de-sac was made, care being taken not to go too far upward and damage the levator palpebrae muscle. Near the margin of the inferior eyelid, eight sutures were placed through the skin. When artery forceps were fixed to these sutures, they pulled the inferior eyelid downward, disclosing and exposing its bare inner surface. These sutures were also indispensable in inserting the mold at a later stage of the operation. For the same reason three sutures were placed near the margin of the superior eyelid.

Finally, a large canthotomy was performed, and the hemorrhage that followed carefully controlled.

The sutures were relaxed, and a form of dental wax (stents) was molded to fit the newly formed conjunctival sac, now denuded of conjunctiva. The central part of mold was made more concave than the curvature of the cornea so that it could not touch and damage its surface. A small hole in the center, 5 mm. in diameter, made observation of the cornea possible during aftertreatment, as soon as the palpebral fissure was reopened (see later). Care was taken that the mold fitted the cavity as accurately as possible and that the eyelids could be closed over it without any tension. The margins of the mold were made rather thick in anticipation of the considerable postoperative shrinkage of the cavity. Hemorrhage was carefully controlled, and tears were prevented from flooding the receptive area by strips of gauze. Lacrimation was moderate, although, fortunately, not absent. The mold was wrapped in sterile gauze and laid aside.

In the next stage of the operation, artery forceps were fixed to the sutures of the inferior eyelid, pulling it downward by their weight and exposing the inner surface, completely devoid of epithelium. The superior eyelid was fixed in a tarsus-clamp forceps, everted so that the normal, tarsal-conjunctiva donor area was revealed. A fine needle was introduced into this conjunctiva; it was raised, but because of the firm fixation of the conjunctiva to the underlying tarsus, the movement was very limited. Consequently, only a very small cone of conjunctiva was obtained; this was cut with a razor blade. This technique was ideal, but it was much easier to snip the small cone off with iris scissors. These small conjunctival snips were grafted on the inner surface of the inferior eyelid and against the eyeball itself, in its inferior

half. Other conjunctival grafts were snipped from any area where a conjunctival lining was present. All these grafts were carefully transplanted, one by one, directly from donor area to the receiving surface. Gentle pressure was applied by a cataract spatula so as to flatten out the grafts and remove excess blood, or serum, and tear fluid. After the last graft had been placed in position, the wound was allowed to dry for a few minutes. The grafts adhered quite well to the underlying tissue. The mold was now reinserted, care being taken to displace as few of the grafts as possible. The sutures of the superior and inferior eyelids were helpful in inserting the mold and in closing the eyelids over it, leaving the tiny grafts *in situ*. The traumatized surfaces of the margins of the eyelids, caused by the cleavage of the blepharorrhaphy in the first stage of the operation, were sutured again.

Figure 2 was taken 12 days after the operation, after the palpebral fissure was reopened. The mold is clearly visible. It was removed on the fourteenth day. On the temporal side, the result was far better than I had expected. However, at the extreme nasal side, in the region of the canaliculus, where the cul-de-sac was very shallow, the result was not so good. This was due to the fact that we failed to free the bulbus sufficiently at this spot and at the whole nasal side under the caruncula lacrimalis. Consequently, the movements of the eye toward the temporal side were still restricted, whereas they were excellent in all other directions. In the future, sufficient freeing of the bulbus will not be neglected. To do this will require more conjunctival grafting, but there seems to be little objection to taking some grafts from the conjunctiva of the other eye, especially in cases where vision is good

and limitation of ocular movements would cause trouble. This could be attempted in new cases in the granular stage.

Recovery was uneventful. Probably because of the ideal physiologic nature of the grafts, there was very little secretion. Nineteen days after the operation, the patient was able to return to work. In the right eye he had light perception and even accurate projection. He was very glad to know that he could see with this eye and that he would be even better off if an operation were performed (iridectomy). However, binocular vision was under this disadvantage: The image of the normal left eye was disturbed by the blurred, distorted, obliquely placed image superimposed upon it by the right eye; a disturbance which probably would be increased if an iridectomy were performed, causing the image of this eye to become more obtrusive. Moreover, the cosmetic effect was unsatisfactory, since dense scar tissue made the inferior part of the cornea whitish.

For these reasons, the original procedure, determined upon prior to the operation, was carried out, and a colored contact glass was inserted. The results, both subjective and objective, were good (fig. 3). The patient has to be content with the knowledge that, should his left eye be lost by another accident, he would be able to help himself with the right eye, now excluded from use.

SUMMARY

Treatment of a case of total symblepharon of the inferior eyelid is described. By means of small "seed" grafts from the conjunctiva of the same eye, in combination with a (stents) mold and a contact glass, the results are as illustrated in figure 3.

✓IMPLANTATION INTO TENON'S CAPSULE*

SIDNEY A. FOX, M.D.
New York

It is generally accepted by ophthalmologists that, when an eye has been removed, the socket for both physiologic and cosmetic reasons should have some sort of an implant. This concept has been so well established that it requires no documentation. Nor is there any intention to discuss here the respective merits of the various shapes, sizes, and materials used for this purpose. My aim here is to report the method used and the results obtained in making a large series of implants because it is probable that the experiences of ophthalmic surgery in war will be of interest to all ophthalmologists.

In the 22-month period from February 1, 1944, to November 30, 1945, there were 144 implantations into Tenon's capsule at this hospital. Of these, 67 immediately followed enucleation. The other 77 were delayed or secondary implants for sockets from which the eyes had been removed overseas from 3 to 14 months earlier. None were lost.

In the first 27 cases Mule's vitreous spheres were used. Tenon's capsule was closed with a 3-0 chromic purse-string suture, and the conjunctiva was closed with a 4-0 black-silk interrupted stitch. In all subsequent cases, a plastic-ball implant was used exclusively, made of the material that was used by the Army in the manufacture of plastic-eye prostheses, a polymer of methyl methacrylate. In these latter cases also, the crossed mattress suture much as described by Kirby¹ was used to close Tenon's capsule and a running black-silk suture was employed for conjunctival closure. In the vast majority of cases, the 16 mm. ball was used. This is an unpolished, solid plastic ball

with small round indentations as illustrated (fig. 1). In only seven cases was either an 18 mm. or 14 mm. implant used. The weight of the ball is approximately

Fig. 1 (Fox). Plastic balls used for implantation into Tenon's capsule. The sizes are 18, 16, 14, and 12 mm.

three times that of the homologous glass sphere. No untoward reactions to the plastic material were noted. Some of these cases were under observation for 12 months or longer.

TECHNIQUE

Enucleations. The patient is given 1.5 gr. of nembutal the night before operation. In the morning 4.5 gr. of sodium amytal is given one hour preoperatively. Just before the patient is wheeled into the operating room, morphine sulphate (0.25 gr.) together with 1 c.c. of prostigmine methylsulphate (1:2,000) is administered intravenously. As shown by Slaughter,² prostigmine has been found to enhance the action of the morphine. Locally the eye is anesthetized by a 0.5-per cent instillation of pontocaine and a retro-

*From the Eye Center, Newton D. Baker General Hospital, Martinsburg, West Virginia.

bulbar injection of 4 c.c. of 1-percent novocaine with adrenalin. More may be given if necessary. The latter anesthetic is also used to balloon up the conjunctiva. This combination has worked so well that general anesthesia has been found unnecessary.

The conjunctiva is circumcised close to the limbus and undermined into the

Fig. 2 (Fox). Type of conformers placed into conjunctival sac postoperatively. At first two holes were drilled in them for drainage. This was discontinued when it was found that the conjunctiva tended to protrude through these openings.

fornices and canthi. The four rectus muscles are isolated on a muscle hook and cut close to the sclera at their insertions with a minimum of surgery and without freeing their fascial attachments. An exception to this is made in the case of the external rectus, a 4 mm. stump of which is left attached to the sclera and clamped in a small hemostat to facilitate subsequent handling of the globe. The blepharostat is then placed under the conjunctiva, and the globe proptosed. At this time, the oblique muscles are identified and cut close to the sclera, and all other adhesions to the sclera cut as far back as can be reached. The wire loop of a tonsil snare is then passed over the globe, tightened, and pressed downward. At the same time, an assistant pulls the globe upward by making traction on the hemostat attached to the stump of the external rectus muscle, and the eye is cleanly enucleated.

Hemostasis is obtained by a gauze strip folded into Tenon's capsule and by digital pressure.

The edge of Tenon's capsule is then grasped by four mosquito clamps opposite the insertions of the rectus muscles. Two double-armed mattress sutures of 3-0 chromic catgut are passed through the edge of Tenon's capsule from below upward diagonally as follows:

From the angle between the external and inferior recti to the angle between the internal and superior recti. And from the angle between the internal and inferior recti to the angle between the external and superior recti. A 16 mm. plastic ball is then inserted into Tenon's capsule by means of an introducer, and the sutures firmly tied. The conjunctiva is closed in the horizontal meridian by a 4-0 black-silk running suture knotted at both ends. A slightly curved plastic conformer (fig. 2) with the concavity inward is inserted, and a monocular pressure bandage applied.

The patient is kept in bed for 24 hours. The bandage is removed on the fifth postoperative day, the socket cleansed, the conformer reinserted, and a simple patch reapplied daily for two or three more days. A conformer is worn in the socket until a permanent prosthesis is obtained three or four weeks later.

Secondary orbital implants. Preoperative preparation and anesthesia is exactly the same as for enucleation. Due to the large amounts of fibrous tissue sometimes encountered in traumatic cases, more retrobulbar anesthesia is often necessary. The conjunctiva is opened horizontally in midline and undermined. After identification, a similar opening is made into Tenon's capsule and enlarged with scissors until good exposure is obtained. A large Kelly clamp is then inserted and opened gently so that Tenon's capsule is stretched sufficiently to assure adequate

space for the implant. This is important. From here on, the technique is the same as described above for enucleations.

DISCUSSION

So many implants into Tenon's capsule without extrusion are hard to attribute to any one factor. There is nothing particularly new in any single step of the above outlined technique. As a matter of fact, due to the pressure of work the simplest and shortest procedures were adopted early as time savers. Thus the purse-string was discarded for the simpler, crossed mattress suture for closing Tenon's capsule; the interrupted suture for closing the conjunctiva was abandoned in favor of the simpler running suture. Parenthetically, it might be stated here that motility of the stump—or the lack of it—did not seem to be influenced by the type of closure used. In the case of enucleations, the use of the snare instead of the standard enucleation scissors is, I believe, an important factor. The advantage of using the snare is that it crushes the optic nerve and its vessels instead of cutting them cleanly and thus facilitates hemostasis and obviates secondary hemorrhage. Ophthalmologists who have not used this method of amputating the globe will be agreeably surprised by the minimal amount of bleeding in most cases.

In the case of secondary orbital implants, a factor which cannot be stressed too much is the use of sufficient dissection to give the implant ample room. Another important factor, in both enucleations and secondary implants, is the use of a conformer in the socket in conjunction with a firm pressure dressing which

is undisturbed for five days. As shown in figure 2 this conformer varies in shape from the one first reported by Gifford³ for this purpose. The effect, however, is the same, and my experience fully corroborates Gifford's opinion that postoperative chemosis is reduced by its use.

I do not believe that the kind of implant or sutures used makes much difference in retention of the implant.

CONCLUSIONS

1. In the 144 cases reported I believe that the factors preventing extrusion of the implant from Tenon's capsule after enucleation were: (a) use of the snare instead of the scissors for amputating the globe, (b) use of a conformer together with a firm pressure bandage which is undisturbed for five days. The latter prevents chemosis and assures healing of tissues in proper position.

2. In the case of secondary orbital implants, another factor is important: Sufficient dissection to assure that the implant has ample room in Tenon's capsule and does not have to be forced in.

3. I do not believe that the type or shape of implant used, nor the kind of suture, are of much importance in retention of an implant.

Recent advances in techniques will undoubtedly pave the way for ultimate improvement in type, quality, and mobility of orbital implants and prostheses, especially following immediate enucleation. But for some time to come, and until newer procedures are perfected, the method outlined above will be found adequate and effective.

NOTES, CASES, INSTRUMENTS

ORBITAL CELLULITIS FOLLOWED BY TOTAL BLINDNESS

HUGH C. DONAHUE, M.D.

Boston, Massachusetts

The orbit is the site of various pathologic processes, the most common of which are inflammation and neoplasm in addition to diseases which produce changes in position of the eyeball (exophthalmos and enophthalmos). Trauma, emphysema, extension of infection from the adjacent sinuses and eyelids, blood dyscrasias, and infections of Tenon's capsule may produce orbital change. The literature is replete not only with descriptions of the manner in which all of these disease processes may affect the orbit but also with reports of their results and complications. This report will attempt to describe a sequence of events which resulted in total blindness in an eye, surrounded by massively infected orbital tissues and accompanied by tremendous edema and proptosis, and to record my impression as to why total blindness ensued.

A review of the literature reveals that in many instances blindness or partially reduced vision was the aftereffect of various lesions occurring in the orbit. Complications of neoplasm, trauma, infections, emphysema, exophthalmos, and operative interference during the process of treatment have all been cited as predisposing causes of loss of vision but the actual sequence which led to the visual loss has frequently been concealed behind a cloud of generalities. Thrombophlebitis of the orbital blood vessels and excessive stretching of the orbital portion of the optic nerve due to extrinsic pressure on the nerve from surrounding

pathologic processes have often been terms used to give a vague description of the succession of conditions leading to visual loss.

In the case to be discussed, I was able to observe accurately the sequence of events which I believe produced blindness and the intraocular changes which followed. It would be appropriate, however, first to review some of the causes of orbital cellulitis and the pathologic changes that occur.

This clinical entity is usually unilateral and is most commonly due to infection extending from accessory-nasal-sinus disease or infections of the eyelid extending to the orbital tissue through the blood and lymph vessels. The ethmoid and fronto-ethmoid cells are the most commonly involved sinus areas. Inflammation of the orbit may also result from a thrombophlebitis of the facial vein following infections of the eyelid, eyebrow, lip, and nose. Because of the anastomoses that occur between the veins of the superior maxilla, the mouth, tonsils and pharynx, and the deep orbital veins, extension of infection of these tissues to the orbit may easily result. Metastatic abscess of the orbit frequently arises in infectious diseases such as scarlet fever, chicken pox, and influenza. Tuberculosis of the periosteum may produce orbital cellulitis even in the absence of a break in the skin, and subperiosteal abscess following fracture, injury, or operation may also account for it. The pathologic changes that occur in this disease are inflammatory edema, congestion, stasis, and cellular infiltration with or without suppuration. All of these pathologic conditions occur in orbital phlegmon, orbital thrombophlebitis, subperiosteal abscess, and inflammation in Tenon's capsule.

Orbital cellulitis must be differentiated from cavernous-sinus thrombosis, which is usually bilateral, with marked constitutional symptoms and often accompanied by 3rd-, 4th-, and 6th-nerve paralysis; from serous tenonitis, which is usually bilateral, with severe pain and chemosis but with absence of constitutional symptoms; from panophthalmitis, which always includes involvement of the interior eye; and also from erysipelas, actinomycosis, and other infections.

In the case to be recorded, there occurred a primary infection of a lower lid which resulted in an extremely virulent infection of the intraorbital tissues, producing extreme edema of the lids, chemosis, exophthalmos, and limitation of motion of the eyeball. The patient's vision remained unaffected by all these changes until one morning in the second week of his disease when he noted a distinct and substantial loss of sight while testing his vision. Examination revealed no change in the external appearance of the eyeball from the previous day. There was marked exophthalmos and chemosis. The pupil was widely dilated due to mydriasis. The media were clear. However, the fundus showed the typical picture of embolism of the central retinal artery, with considerable edema of the macula, cherry-red spot, and attenuation of the retinal arteries.

The central artery of the retina, a very slender vessel about 0.25 mm. in diameter, comes off the ophthalmic artery close to the optic foramen and is usually accompanied by another branch. It runs forward, first in or outside the dural sheath of the optic nerve, and then crosses the subarachnoid space with its vein and pierces the optic nerve on its inferior and medial aspect about 10 to 20 mm. behind the eye. Surrounded by an extension of pia mater and a sympathetic nerve plexus, it runs forward and upward from cavernous-sinus thrombosis, which is usually bilateral, with marked constitutional symptoms and often accompanied by 3rd-, 4th-, and 6th-nerve paralysis; from serous tenonitis, which is usually bilateral, with severe pain and chemosis but with absence of constitutional symptoms; from panophthalmitis, which always includes involvement of the interior eye; and also from erysipelas, actinomycosis, and other infections.

During the following days the usual sequelae took place; namely, slow and gradual subsidence of the area of edema and ischemia, with atrophy of the nerve head and constriction of the arteries. In my opinion this is probably the course of events that takes place in the majority of cases of orbital cellulitis which result in either blindness or substantially reduced vision and in which atrophy of the optic-nerve head has been reported.

CASE REPORT

Mr. A. C., aged 48 years, a married, American contractor, was first seen by me in January, 1943. At that time he complained of pain, irritation, and tenderness of the lower lid of the left eye of five days' duration. He had been previously seen by another ophthalmologist, who had treated him during the previous week for an hordeolum of this lid.

Examination proved the right eye to be entirely normal. In the left the vision was 20/20. The upper lid was moderately edematous, the lower lid extremely edematous, with branny induration upon palpation. There was marked tenderness and

sisted for three days. Upon the second morning of such drainage, while the eyeball was considerably proptosed, the patient noted loss of sight. Examination of the fundus was made approximately two hours later and revealed the typical clinical picture of embolism or obstruction of the central retinal artery. There was massive edema of the macular area with ischemia and cherry-red spot; the arteries were constricted, the veins overfilled and tortuous. Vision was reduced to light perception.

It was obvious that the area of massive congestion and edema within the orbit had compressed the retinal artery, producing blockage of blood flow and secondary death of the ganglion cells of the retina. During the ensuing several days the infectious process gradually subsided, but the vision in this eye became nil, and the fundus showed the usual changes that occur following obstruction of the central retinal artery.

Two months following discharge from the hospital the patient's external eye was normal in every respect. There was no edema of the lids or conjunctiva. The eyeball had receded into its normal position, ocular movements were normal, as were also the cornea and iris. The pupil was moderately dilated and reacted sluggishly to light. The media were clear. The disc was snow white and atrophic, the macular area somewhat mottled and degenerated without edema. The arteries were threadlike in size and the veins slightly overfilled and tortuous.

It seems apparent that the loss of vision in this case (and probably in the majority of cases in which impairment of vision follows a condition that produces extreme congestion and edema within the orbit together with proptosis of the eyeball) was due to obstruction of the blood flow through the retinal artery brought about

redness over the entire lower lid; and the ciliary in the lower area, were moderately congested. The cornea, pupil, iris, lens, vitreous, and fundus were normal. The intraocular pressure was normal, as were also the muscular excursions. A diagnosis of cellulitis of the lid was made, and immediate hospitalization advised.

The patient was admitted to the Massachusetts Eye and Ear Infirmary, where he was treated for two days with local applications of heat, and with various forms of local antiseptics together with local and systemic doses of sulfadiazine. During this period, penicillin was available in this hospital only to patients running a septic type of temperature. Upon the third hospital day, the edema of the lids increased, the chemosis of the bulbar conjunctiva was more severe, and there also was present a moderate degree of proptosis. Consultants in otolaryngology and infection were called, and it was deemed advisable to treat this patient with penicillin, even though the supply of this drug was being meticulously distributed. Incision through the upper lid into the superior orbit was also made upon two occasions, and small amounts of purulent material evacuated. Upon the fourth hospital day, the patient was running a septic type of chart. Intramuscular and intravenous injections of penicillin were commenced.

At this stage of the disease exophthalmos measured 7 mm. There was limitation of motion of the eyeball in all directions and marked edema and congestion of the lids and conjunctiva. The fundus was entirely normal other than a slight amount of venous congestion; vision was 20/20. Upon the third day of penicillin therapy the septic material which had accumulated in the orbit became purulent, and there was profuse drainage of pus through the upper lid. This condition per-

DISCUSSION

Before evaluating the indications for prisms in this case, it is well to consider the advisability of prescribing bifocals that contain prisms in their segments. It is usually better to avoid such a type of bifocals for four reasons: (1) Such glasses are more expensive than ordinary bifocals; (2) they are more conspicuous than ordinary bifocals; (3) most important, since the near vision is limited to the small segment of the bifocals and, thereby, requiring limited fixation be imposed on the eyes, such limitation may of itself contribute to the production of symptoms. The same prescription in a single-vision glass allows the patient to hold his book in many different positions and is less likely to bring about fatigue; (4) in walking on stairs the prisms would introduce new difficulties in judging distance.

I believe that the best solution in this case would be to give this patient ordinary bifocals for constant wear, and a prism containing single-vision near glasses for prolonged near work. She could utilize the ordinary bifocals for every-day use, since she could have adequate near vision through the reading segments for the purposes usually required. It is true, they would not be so effective for prolonged reading but, for such purposes, the single-vision reading glasses could be used.

It is fortunate that this patient profited by prisms, since the data were not adequate to predict that prisms would help. It would have been important to know whether the near exophoria was measured through the reading glass because, if it were not, we could be sure that the patient had more than 12^{Δ} of exophoria while wearing the near correction. The measuring of a near point of convergence would also have been helpful, and amplitude of fusion measurements were absolutely indicated. Lastly, one might have tried the

by compression and constriction of this artery by external congestion and edema. This cessation of blood flow, verified clinically by the typical fundus picture, is a more logical explanation of the visual loss following orbital cellulitis than are other previously reported possibilities; namely, compression or stretching of the optic-nerve fibers alone.

520 Commonwealth Avenue.

REFRACTION CLINIC*

DISCUSSION BY ALBERT E. SLOANE, M.D.†

Boston.

A woman, aged 49 years, came into the clinic complaining of having particular difficulty with prolonged near vision. She was wearing: O.D., $+0.25D$. sph. \ominus $-2.50D$. cyl. ax. 115° ; O.S., $+0.25D$. sph. \ominus $-2.25D$. cyl. ax. 60° . Add $+1.75$. On checking her refraction, very little difference from the glasses she had been wearing was found. It was noted that she had at distance— 5^{Δ} exophoria, v orthophoria; near— 12^{Δ} exophoria, v orthophoria.

Uncorrected vision was: O.D., $20/50$; O.S., $20/50$. With the correction: O.D., $+0.50D$. sph. \ominus $-2.25D$. cyl. ax. 115° , vision was $20/20$; O.S., $+0.50D$. sph. \ominus $-2.25D$. cyl. ax. 60° , vision was $20/20$. With the addition: $+1.75D$. sph., the patient could read well.

The house officer ordered a single-vision lens for near, incorporating a 2.50^{Δ} base in for each eye. The patient reported two months later, and stated that she was content with her new reading glasses and that she no longer had any discomfort with near vision. She would like to have this prescription incorporated into bifocals so that she can wear them constantly.

† Director of Department of Refraction.

therapeutic test of occluding one eye to determine whether that relieved symptoms.

QUESTIONS

House Officer: Would you not expect much poorer uncorrected vision in a person who had such a substantial refractive error?

Dr. Sloane: I would expect poorer vision, but the ability to read letters on a test card varies with many people for the same refractive error. This ability is probably related to a combination of familiarity with letters and the degree of ease with which the person may have been in the habit of getting about without glasses, a habit which promotes the accurate interpretation of blurs. In examining draftees you will note that many boys having 2D. myopia will vary in their uncorrected vision from 10/200 to 20/50.

SOLUTION

For prolonged near use, the following prescription was ordered: O.D., +2.25D. sph. \ominus -2.25D. cyl. ax. 115°; with a 2.50^a base in for near; O.S., +2.25D. sph. \ominus -2.25D. cyl. ax. 60° with a 2.50^a base in for near.

For everyday wear, these glasses were ordered: O.D., +0.50D. sph. \ominus -2.25D. cyl. ax. 115°; O.S. 0.50D. sph. \ominus -2.25D. cyl. ax. 60° (with the addition +1.75D. sph.).

A FOOT SWITCH TO CONTROL THE ILLUMINATION OF THE REFRACTING CHART*

WALTER H. FINK, M.D.
Minneapolis, Minnesota

A continuous exposure to an illuminated chart during the process of refraction, definitely lessens ocular fatigue, or for short rest periods during the refraction, more accurate concentration is possible on the part of the patient. The foot control can be used with either the projector type of chart or a

Fig. 1 (Fink). The switch is manipulated by pressure of the foot.

friction leads to early ocular fatigue and greater difficulty in concentration. In addition, a certain amount of confusion results in changing lenses when the patient constantly watches an illuminated chart. This apparatus provides an easy control of the illumination of the chart. By

chart is enclosed and painted a flat gray. The illumination is placed just inside the opening in the wall and out of sight of the patient. A movable chart is used, and only one line of symbols is exposed at a time. The movement of the chart is controlled by the examiner seated near the patient. Daylight can be used in the examining room.

AN INSTRUMENT FOR TESTING BINOCULAR VISION*

WALTER H. FINK, M.D.
Minneapolis, Minnesota

The Howard-Dolman apparatus is not practical for the average oculist's office. Since its use provides valuable information, a more practical method should be found. This instrument is suggested as a substitute for it. Although it does not replace the Howard-Dolman apparatus, and its efficiency cannot be estimated in percentage, it gives the examiner—with

Fig. 2 (Fink). The photograph illustrates the arrangement of the recessed chart.

movable chart recessed in the wall. If the nonprojector type of chart is used, it is necessary to recess the chart in the wall 2 to 3 feet, so that when the light is off the patient cannot read the symbols. This is accomplished by having an opening $1\frac{1}{2}$ feet square in the wall and the chart recessed into the next room. The space between the wall opening and the

Fig. 1 (Fink). An instrument for testing binocular vision.

little effort—a comparatively accurate impression of the amount of binocular action. The instrument is simple in design and easily comprehended by young children. It is a quick, convenient check to be used to determine whether or not the patient has binocular action. The method has proved of special value as a routine procedure.

DESCRIPTION OF THE INSTRUMENT

The patient views the targets through two openings similar to a stereoscope except that no lens is used. One-half meter away are four movable vertical wires of variable diameters and one inch in

length. The position of each target is controlled by a sliding rod. These rods vary in length. The patient adjusts the movable target to the proper position by moving the sliding rod back and forth.

Immediately above these targets are four nonmovable vertical wires which are placed in variable positions and which vary in diameter. The object is to align the lower wires immediately beneath the upper wires. The size of the targets cannot be used as a criterion, because the upper wires are smaller or larger in diameter than the lower wires.

DR. MAURICE L. WIESELTHIER, *presiding*

SHADOW CASTING DEVICE IN BIOMICROSCOPY

DR. G. KLEEFELD presented a paper on this subject during the instruction hour.

ZONULAR MEMBRANE AND ITS CHAMBERS

DR. H. MINSKY presented a motion picture on this subject.

EMBRYOLOGY OF THE ZONULE

DR. A. KORNZWEIG said the difficulties associated with the study of the development of the zonule are similar to those which are associated with the studies of all hyaline and glass membranes in the eye. These substances do not stain well, especially when they first appear. They are fragile and are immediately changed by the process of fixation and staining. The most recent theory is that the fibers are derived from the neuro-ectodermal tissue in the same way as the vitreous. This theory attempts to place the origin of the vitreous, the zonular fibers, and the internal limiting membrane of the retina under one common factor. The cell, which is responsible, is believed to be the Müller cell. It gives rise to the internal-limiting membrane through the medium of its footplates. The vitreous body, itself, may be a product of the Müller fibers because the internal-limiting membrane and the vitreous are so intimately attached. Since the ciliary body is formed by an extension forward of the margin of the optic cup, the inner layer

(the non-pigmented retinal layer), also gives rise to fibrils which, eventually, become the zonular fibers. The cells of the inner layer, which are responsible, are believed to be similiar in type to the Müller cells in the retina.

Three slides were shown. Two were diagrammatic; the third was a microphotograph of the zonular region of a four-month embryo.

TWO CASES OF DEHISCENCES OF THE ZONULAR LAMELLA IN CONTUSIONS

DR. MORRIS DAVIDSON described two cases. The first was the case of a man who was struck in his left eye by a door-check spring, in 1940. Hyphemia subsequently developed. Six months later, a tenuous, bluish membrane was found. It projected from the very small, deformed pupil and was seen floating in the anterior chamber. The iris root transilluminated, lower temporally. Maximal dilatation of the pupil disclosed a temporal lens subluxation and an incomplete choroidal rupture, lower temporally. The membrane was attached to a curved, jagged line running from the 5- to the 7-o'clock positions on the anterior lens capsule. There were no zonular fibers nor tags of them. The serrated lens equator was clearly visible, as well as the ciliary processes. An anteroposterior, subcapsular opacity was noted during the course of subsequent observations. When seen four years later, vision was still 20/200, with little increase in opacification. An interesting feature of the case was the gradual increase of myopia. A minus-two sphere combined with a minus-two cylinder corrected the refractive error when first seen; this increased gradually in six months to

a minus-five sphere with the same cylinder.

The second case was that of a 41-year-old man whose left eye was struck by a large chip, in 1943, with development of hyphemia. Six months later, on maximal dilatation, an almost complete annular detachment of the zonular lamella was found. The ring of the exposed lens capsule retained its shagreen for about a year, when it disappeared with the increasing subcapsular opacification and formation of folds in the sector where the membrane was attached.

In neither case, was there hypertension noted at any time.

PRACTICAL CONSIDERATIONS IN BIOMICROSCOPY OF THE ZONULA

DR. MILTON L. BERLINER said that there has recently been renewed interest in the morphology and dynamics of the zonular system, especially because of the increased popularity of intracapsular cataract extraction. The original concept of the zonular system's membranous structure is being revived, while the belief that it is a collection of fibers permitting free passage of the aqueous fluid of the posterior chamber is no longer universally held. The individual fibers making up the system do not end at the peripheral ridges or in the valleys between the ciliary processes. Most of them reach almost to the ora serrata and are 6 to 6.5 mm. long. The ciliary processes separate the zonule into single bundles.

Biomicroscopy, in cases where the zonule is exposed sufficiently to be accessible, is performed under high magnification, and with intense direct focal illumination in order to make apparent, by the Tyndall phenomenon, otherwise invisible structures. The pupil should be dilated, if possible, and the room darkened. Slight

movement of the beam accentuates visibility of the fibers which, even in favorable cases, can be seen only as far as the tips of the ciliary processes. The zonular fibers appear as delicate threads which glisten when viewed by specular reflection. The fibers inserting on the anterior aspect of the lens extend far axially from the equator, while posteriorly they insert closer to the equator. When the fibers are visible, it is rare to find them entirely intact, the bundles being spread apart or missing in certain areas. Frequently, torn fibers can be seen curled up at their attachment to the capsule. In other cases small white dots on the capsule mark their previous sites of attachment. Unbroken fibers attached to luxated or pathologically shrunken lenses attest to their elasticity.

It is possible that ectopia lentis, microphakia, and sphenophakia are due to a hereditary defect in the anlage of the zonule, with the fibers being aplastic or stretched. In those cases in which there is considerable tearing of the anterior zonular fibers, the anterior surface of the lens may be more curved than normal, emphasizing importance of the fibers in accommodation. When the equator of the lens is visible, irregularities can be seen at the margin where the zonular fibers are torn, indicating a retraction of the lens in the absence of zonular traction.

After inflammation—for example: iridocyclitis, if shrinkage of the lens or iris coloboma (congenital, operative, or traumatic) permits inspection—alterations in the zonule are seen. Fibers may be taut, stretched, torn, or absent. The fibers may be sheathed by pigmented or whitish deposits. In old iridocyclitis, heavily pigmented fibers appear like miniature brown cords of rock candy. These changes, indicative of zonular destruction, explain the ease with which complicated cataract can be extracted intracapsularly. They

also explain spontaneous luxation of cataracta complicata.

The frequency of dislocation after trauma shows the readiness with which the normal zonule tears; the negative pressure of the patellar fossa and the hyaloideocapsular ligament being of lesser importance in maintaining the position of the lens. When the lens is displaced, inequalities in the depth of the anterior chamber will be noted, and the edges may become undulated. Iridodonesis and phacodonesis may be present. Traumatic iritis and hemorrhage may result in deposits on the fibers. Vogt has described a case in which, after a perforating injury, there was the unusual picture of separation at the equator, by fluid of the capsule from the underlying lens substance. This was the result of increased zonular traction.

Traumatic detachment of the zonular lamella was first seen and described by Meesmann, in 1925. He noted in the area of lens displacement a "free-floating, crinkled membrane" concentric to, but separated from, the lens margin. Undoubtedly, more frequent biomicroscopic examinations of hereditary, spontaneous, or traumatic displacement of the lens will reveal such separation of the zonular membrane. Its traumatic detachment at the equatorial region in this manner proves that its nature is individual and unlike the flaky, axial separation caused by age or heat-cataract.

Discussion. Dr. Henry Minsky pointed out the possible relationship of the true concept of the zonular structure to the theory of accommodation, to the mechanism of spontaneous retinal detachment, and to some operative procedures for the relief of hydrophthalmos.

It is possible to combine the Helmholtz theory of accommodation with the views held by Tscherning, if we consider that the anterior and posterior zonular leaves be-

come relaxed, while the hyalo-zonular leaf remains taut during the active part of accommodation.

It seems, from the intimate insertion of the zonular fibers into the retina and the hyaloid, that the longer it takes to rupture the zonular fibers, the more certain is it that an extracapsular operation should have been performed. If the zonular fibers are ruptured quickly and easily, the intracapsular operation is the one of choice.

None of the four theories outlined by Duke-Elder, in considering the mechanism of detachment of the retina, succeeds in explaining the production of a spontaneous detachment resulting from sudden generalized muscular strain such as occurs in stumbling, sneezing, wrestling, or stunt flying. If we assume in these cases that, with the protective bracing of the whole body, there takes place a spasm of the ciliary muscle, we can understand how a previously diseased spot in the retina could be transformed into a hole, since the retina and hyaloid are suddenly pulled forward by means of the insertion of the zonular fibrilla in these two structures. The crescentric holes, seen clinically, all have their concave edges face forward. In the experimental production of such holes in the retina, Dr. Minsky has found that the concavity always faces the direction of pull. Since the ciliary muscle is the only part of the eye that can exert such a pull, it seems reasonable to assume that it plays a significant role. It might, therefore, be desirable to immobilize the ciliary body in the meridian of the tear by surface diathermia, as well as to seal off the hole.

In hydrophthalmos, the zonular chamber is enormously dilated. In one case, the sclera was trephined 5 mm. back of the apparent limbus, and the zonular chamber was opened without the loss of vitreous through a perforation of the ciliary body.

The tension was reduced to normal, and the diameter of the cornea was decreased from 16 to 12 mm. The scleral operations recently described by Terry and by Lehrfeld are probably related to the easy exit of aqueous from the zonular chamber.

The structure of the zonule of Zinn can be appreciated only when the observations of the gross anatomy are in complete reciprocal agreement with the interpretations of the microscopic picture. When the uveal coat is removed from the underlying structures in the fresh eye, it is found that the zonular fibers are attached more intimately to the vitreous and to the retina than to the ciliary body from which they arise. After the complete removal of the retina, a serrated white line is seen in the hyaloid at the site of the ora serrata—the hyalo-retinal ligament. If the lens-vitreous body is suspended by sutures placed in the zonular fibers, a hammocklike cradle of the zonular fibers, in which the lens rests and from which the vitreous hangs, is produced. This demonstration proves that the zonular fibers are unquestionably inserted into the hyaloid by means of the hyalo-retinal ligament.

This ligament can be recognized in microscopic slides as the plaque filling the angle between pars plana and the ora serrata. It is made up of zonular fibrilla which go to form the zonular fibers coursing on the face of the vitreous—the hyalo-zonular leaf (the “innermost” fibers of Salzmann, the “fibrae orbiculposteriocapsulares” of Garnier). The hyalo-zonular leaf forms the posterior boundary of a real aqueous space—the zonular chamber (“orbicular space” of Garnier)—and terminates in the ligamentum hyaloidea capsulare on the posterior surface of the lens. The anterior limit of this zonular chamber is bounded by the posterior and anterior zonular leaves. It may contain products of inflam-

mation and is enormously enlarged in cases of hydrophthalmos.

Dr. Berliner pointed out that Dr. Minsky indicated that there may be zonular fibers originating from the ciliary processes. He thinks most of the fibers come from the pars plana. Since some of the fibers branch as they come into the area of the ciliary processes, they may, at times, seem to run from ciliary process to ciliary process. However, they do not form actual communications between ciliary processes themselves. This can be verified in preparations made after the technique of Eggers, in which the fibers can be lifted by a glass rod. Dr. Minsky also suggested that zonular pull at the ora during accommodation may be a factor in retinal separation. According to this theory, hyperopes should be more susceptible to retinal separation than myopes.

DR. W. D. STINSON, *presiding*

IDIOPATHIC RETINAL DETACHMENT IN PREGNANCY

DR. J. WESLEY MCKINNEY reported the case of Mrs. C. P. McK., who was seen the first time for this illness, June 24, 1944. She gave the history that one week before she had bumped her head and broken the left lens of her glasses. The blow was received on the left forehead. Immediately afterward a black spot appeared before the left eye. The night before examination, the vision became much impaired. She was seen Saturday afternoon at the hospital, and a large bullous

detachment was found involving almost the entire temporal retina. No tear was made out at this time. The patient did not care to remain in the hospital and, consequently, was sent home to lie on the left side with both eyes padded. Two days later when she reported to the office, the retina was found to be completely re-attached and looked in no way abnormal. No tear could be made out. Vision was 6/9, mostly. After lying in bed for two weeks with both eyes padded, she was given pinhole glasses which she wore for two months. Vision improved to 6/7.5, and observations at intervals revealed no change in the condition of the retina. On October 30th, however, the temporal periphery of the retina again became detached. The patient had been in bed with pads on both eyes for 10 days before she came in for this examination. There was, at this time, a minute, slitlike tear $4\frac{1}{2}$ disc diameters from the ora on the horizontal meridian. The detachment did not reach to the macula, and the retina was not elevated very high. The patient refused operation and remained in bed until the retina again became flat. She wore pinhole glasses for another two months. Gradually, it became very difficult to see the tear, and the retina maintained a perfectly normal appearance. Soon after the last episode of detachment, the patient became pregnant. The retina, however, remained apparently normal until May 2, 1945, when she was about seven months pregnant. At this time, the retina again became detached in the temporal area. A large bean-shaped tear could be seen. The diathermy operation was performed May 5, 1945. On May 10, five days postoperative, she went into labor and was delivered of a premature infant which did not live. The retina remained attached and, at the present time, the vision is 20/20, mostly, and the field is full.

CATARACT EXTRACTION WITH SECONDARY GLAUCOMA

DR. E. C. ELLETT reported the case of Mr. W., aged 42 years, who was operated in December, 1944, for cataracts in both eyes. The opacity was mostly posterior capsular, the near vision being J19. The fundi could be seen, and the veins were tortuous, but not full. Tension was normal. A simple extracapsular operation was done in each eye, three days apart. Spontaneous anterior-chamber hemorrhages occurred in the right eye on the sixth day, and in the left eye on the seventh day. The patient left the hospital two weeks after the first eye was operated upon and used atropine in each eye once a day. He returned in two weeks with tension of 41 and 52 mm. Hg (Schiotz). Vision was 6/6 and 6/24. Under miotics, the vision became normal. The tension remained high for a while but came down in a week to 25 mm. (O.U.). In May, the tension was still down, but there was a thin secondary membrane in each eye and some reduction of vision in the right eye for near (J4). A Wheeler capsulotomy was done on each eye in October, 1945. There has been no trouble with O.S. except that a miotic is necessary to keep down the tension which once went to 32 mm. Immediately following the capsulotomy, the right eye became very soft; tension was 7 mm. Under atropine, it rose in about three weeks to 40 mm., and miotics do not reduce it. On November 24th, vision was: O.U. 6/6 and J1; tension was 40 and 25 mm., the eye grounds were normal, and the fields were not disturbed.

METASTATIC CARCINOMA OF THE CHOROID

DR. ELLETT reported the case of Mrs. W., aged 44 years, who was seen in April, 1945, with the history of a blur in the right eye for two weeks and a diagnosis

of retinal detachment. Vision was 6/60, improved to 6/9. The whole field was blurred, and there was a central reactive scotoma. She had had the right breast removed in 1938, followed by X-ray treatments and no further trouble. The left eye was normal. Pupils were equal and active. The right eye showed a hyperopic blonde fundus. In the region of the ascending temporal vessels, 1 disc diameter from the disc, a white elevated area was visible under and along the vessels. It extended down toward the macula. This area was fairly well-defined. It was seen with a +5 lens. It was yellowish white with no pigment. Transillumination was negative. Tension was 20 mm. Hg (Schiotz). She was given X-ray treatment to the eye. During the summer of 1945, she died from multiple metastases in her chest.

CHOROIDAL DETACHMENT

DR. ELLETT reported the case of Mrs. C., aged 58 years, who had a combined intracapsular extraction, O.D., on June 26, 1945, and the same operation O.S. on July 2. The left eye healed without incident and vision was 6/6 and J1. On July 9th, the 13th postoperative day, the chamber in the right eye was seen to be very shallow, and a three-lobed detachment of the choroid was seen, the lobes being in, down, and out. Vision was 6/7.5. On October 22nd, the detachment was still present, and there was a small cystoid area at the center of the wound. This was treated once with trichloroacetic acid. On November 5th, when the patient was next seen, the detachment had disappeared, and vision was normal with glasses.

A CASE REPORT OF BUPHTHALMOS

DR. P. M. LEWIS and DR. G. M. WALLACE presented the case of M. A., a colored girl four years of age, who was seen in consultation with the pediatric

department of the John Gaston Hospital on December 8, 1945.

The patient's ophthalmic history began at the age of one, at which time her parents first noticed that the left eye appeared larger than the right eye. Since that time the left eye had progressively increased in size; to their knowledge the eyes had never been red or inflamed.

Ocular examination revealed relative vision in the right eye to be identity of objects. There was questionable vision in the left eye. By general inspection, one gained the impression that the left eye was proptosed, larger than normal and exotropic. The dimensions of the right cornea was 12.5 mm., horizontally, and 12 mm., vertically. Corresponding measurements of the left eye were 15 mm. and 14 mm. The depth of the anterior chamber of the right eye appeared normal; however, the depth was markedly increased in the left eye. The cornea of the right eye was transparent, but that of the left eye appeared hazy. It was 2 mm. above the center. Opacity, measuring 1.5 mm. by 1 mm., was present. Tension is either eye was not increased by digital examination. Fundoscopic examination of the right eye did not reveal any abnormality. Similar examination of the left eye revealed the disc to be cupped markedly and a marked thinning of the retina. These conditions were seen best with a minus-25 lens in the ophthalmoscope.

Diagnoses made by the pediatric department were: hydrocephalus, upper-respiratory infection, umbilical hernia, dwarfism, mental retardation, and rickets.

BILATERAL SIMPLE GLAUCOMA

DR. M. B. SELIGSTEIN presented a colored man, aged 59 years, who had noticed a skim over his left eye and failing vision in both eyes. He was hit over the right eye with a piece of stove wood

many years ago, and had not seen out of this eye since that time.

Examination showed a large cupping of both optic nerves. Perimetric fields were: L.E., small amount of concentric vision, up to 5 and 10 degrees; R.E., could not be taken. Tension with the tonometer was 32.5 mm. Hg (Schiotz). Vision was: R.E., light perception; L.E., 20/400. The tension was reduced by myotics in the left eye, only.

On September 8th, an Elliot's trephining operation was performed on the left eye, and an iridencleisis on the right eye. On October 6th, the tension was 18 mm. in the right eye, and 22 mm. in the left eye. The patient was last seen on November 15th, when tension had dropped to 8 mm. in both eyes. A spoke-wheel cataract had formed in the right eye. With a -1.25D. cyl. ax. 90°, vision in the left eye was improved to 20/200. There was a slight enlargement of the field of vision, eccentric, from 10 to 38 degrees on the lower-temporal field and 38 to 35 degrees on the upper-temporal field.

SERPIGINOUS ULCER OF CORNEA

DR. PHILIP MERIWETHER LEWIS presented a white man, aged 56 years, who was still under treatment in the hospital for a severe ulcerative keratitis.

This man was a mechanic who, on December 1, 1945, got a piece of iron rust in his left eye. The rust was removed, apparently cleanly, the following day by a general practitioner. The next day pain in the eye became severe. When first seen, exactly three days after the injury, a purulent ulcer was present. A deep crescent-shaped area of keratitis surrounded the centrally placed ulcer.

The ulcer was scraped out and cauterized, foreign protein, sulfadiazine, and penicillin were given, and the latter used

locally. Seven hours later the eye was so much worse that the anterior chamber was opened. Because of the ulcer's location and extreme severity, a Saemisch section was done. Thereafter, the wound was reopened daily. Penicillin, locally, and 20,000 units, intramuscularly, were given every three hours. Typhoid H antigen, intravenously, and sulfadiazine, orally, were also administered. Considerable improvement had occurred so that when presented, seven days after treatment was started, the cornea was clearing, and there was no hypopyon.

Clinically, this ulcer appeared to be a pneumococcic infection, but cultures failed to reveal the organism. A few Staphylococci albus and an unidentified Gram-negative bacillus were the only organisms grown in two attempts. The extreme rapidity and severity of the infection following the penetration of the cornea by a metallic foreign body were the unusual features of this case.

SYMPATHETIC OPHTHALMITIS

DR. HAROLD KUSHI (by invitation) presented a case report of sympathetic ophthalmitis following cauterization of an iris prolapse with the Ziegler cautery.

E. G., a white man, aged 51 years, was admitted to the hospital on October 8, 1945, at which time a simple intracapsular cataract extraction with peripheral iridotomy was performed in his left eye, followed in five days by a similar extraction in his right eye. No vitreous was lost at either extraction. During the removal of the corneo-scleral sutures from his left eye on the eighth postoperative day, partial iris prolapse developed. The following day a corneo-scleral suture was placed over the prolapse, and the prolapse was cauterized with the Ziegler cautery. Healing was uneventful, and the patient was discharged on the 15th postoperative

day. The media appeared clear, and the fundi looked normal at the time of discharge. Atropine was prescribed for home use.

About a month after leaving the hospital, the patient began having pain in his left eye. He was seen soon after and admitted to the hospital for treatment and observation. On entry, both eyes were markedly injected. Tension was normal; cornea and aqueous were clear; irides thickened; and pupils mid-dilated. Posterior synechiae were present in the left eye, and vitreous opacities in both eyes. Early vascularization of the left iris could be seen. No keratitic precipitates were seen with the slitlamp. Vision was perception of hand movement.

To date, the patient has had a total of 500,000 units of penicillin, 18 gm. of sulfadiazine, 4 injections of Typhoid H antigen totaling 250 million units, sodium salicylates, and, locally, atropine neosynephrine in a 10-percent emulsion. Improvement has not been marked. Pain is less than on entry to the hospital, and the patient states that his vision is better than on entry. Objectively, the findings have remained the same. A few keratitic precipitates are now visible in both eyes. The question arises as to whether this case is one of sympathetic ophthalmia resulting from the cauterization of the iris prolapse. Any suggestion as to further course of treatment and prognosis would be appreciated.

CHICAGO OPHTHALMOLOGICAL SOCIETY

December 17, 1945

PETER C. KRONFELD, *president*

(Held at the Illinois Eye and Ear Infirmary, Chicago)

CLINICAL MEETING

COLOBOMA AND ECTOPIA LENTIS IN ARACHNODACTYLY

DR. THEODORE C. ZEMAN presented a white woman, aged 20 years, who has spent all of her school days in sight-saving classes. She presented herself at the Illinois Eye and Ear Infirmary with a retinal detachment in her left eye which had occurred shortly after the extraction of an ectopic lens four months previously.

In addition to the symptoms of arachnodyly, the patient showed, in her right (unoperated) eye, an ectopia lentis in the upward and lateral direction. Upon dilation of the pupil to a diameter of 5 mm., the lower-nasal equator of the lens came into view. Instead of being circular, its visible portion had the shape of an octagon which, according to the literature, is a rare congenital deformity interpretable as multiple colobomas. The zonule was visible around the entire nasal border. The posterior segment of this eye was also unusual in that it showed a partial optic atrophy without apparent cause.

NONSURGICAL CURE OF A RETINAL DETACHMENT WITH TEARS

DR. THEODORE C. ZEMAN presented a white woman, 30 years of age, who came to the Illinois Eye and Ear Infirmary in March, 1945, with the complaint of an orange-colored film over her left eye of a few days' duration. At that time the cor-

rected vision of her right eye was: 20/30 with a $-3.00D.$ sph. $\ominus -1.00D.$ cyl. ax. 175° ; L.E., 20/200 with a $-3.25D.$ sph. $\ominus -1.00D.$ cyl. ax. 170° . The left had always been the weaker eye. Examination of this eye revealed the presence of a retinal detachment with a high degree of elevation, occupying the sector from the 10:30- to the 4-o'clock positions. Two small tears were present in the 1- and 2-o'clock positions respectively, 10 disc diameters from the posterior pole. No signs of an active or inactive uveitic process could be seen at that time. Under rest in bed and by use of pinhole spectacles, complete reattachment occurred within 11 days and has persisted up to date. The patient wore pinhole spectacles and refrained from strenuous body movements for another month. At first, no reason for this reattachment in the presence of frank tears could be recognized. Now it is apparent that each tear, though still open, is surrounded by fine chorioretinitic changes. The corrected vision in this eye is now 20/50.

BILATERAL PULSATING EXOPHTHALMOS FOLLOWING HEAD INJURY

DR. BENJAMIN E. LYONS presented a 59-year-old white woman who had been struck by a taxi two months before, after which she was unconscious for 24 hours. During her two-week period of hospitalization, she was found to have a right-parietal linear skull fracture. Since the fragments were in good approximation, the patient was treated only symptomatically. The complaints during her stay in the hospital were severe headache, diplopia, and a constant, loud, to-and-fro swishing and roaring head noise. Two weeks later, after going home, she noted that her left eye was starting to swell and protrude. This was followed in two weeks by a similar process in the right eye.

She was admitted to the Illinois Eye

and Ear Infirmary with bilateral exophthalmos, that in the right eye greater than in the left, associated with a large, red, indurated swelling of the conjunctiva of the right lower fornix. The left eye revealed only a small amount of conjunctival chemosis. There was a slight pulsation of both globes coincident with the pulse beat, which was accompanied by a to-and-fro, high-pitched, blowing bruit heard best in both temporal and right mastoid regions. There was a right papilledema of four diopters, a right total ophthalmoplegia, and a left partial external ophthalmoplegia.

This patient was presented as a case of pulsating exophthalmos, probably caused by a traumatic arterio-venous fistula of the right internal carotid artery in the cavernous sinus.

BILATERAL OPTIC ATROPHY DUE TO MENINGIOMA

DR. BENJAMIN E. LYONS presented a 37-year-old housewife who accidentally noted complete loss of the right vision 14 years ago, 8 months after an episode of mumps and right Bell's palsy. She consulted an eye physician who told her only that nothing could be done in the absence of light perception.

In May, 1945, she first came to the Illinois Eye and Ear Infirmary, complaining of blurred vision in the opposite eye. Examination revealed right facial nerve weakness, bilateral primary optic atrophy, right exotropia. Vision was: R.E., no light perception; L.E., 20/30+2, with a generally constricted visual field (5° above, 25° temporally and below, 10° nasally). X-ray studies showed: increased sclerosis of the anterior clinoid processes and thickening of the floor of the skull; also, moderate sclerosis and thickening of the inner frontal table. This was attributed to a developmental

anomaly and thought not to be clinically significant.

The patient was then referred to the Department of Neurosurgery at the University of Illinois where further X-ray studies were made and interpreted as showing destruction of the right sphenoid wing in addition to hyperostosis of the tuberculum sellae. Exploration of the skull was carried out in September, 1945, and an extensive meningioma of the right optic-nerve sheath was removed.

This case illustrates the importance of repeated X-ray studies of the skull in cases of unexplained atrophy of the optic nerve.

CONGENITAL TOXOPLASMOSIS

DR. HENRY N. RICCI presented a 13-year-old girl with a history of an acute febrile condition and convulsions at 21 months for which she was hospitalized. At this time, fundus lesions were noted and, 1½ years later, extensive bilateral chorioretinitis was found.

The convulsions were nonepileptic in nature, there being no aura, no loss of consciousness, no frothing, nor tongue biting. The attacks lasted from 10 to 20 minutes, with the patient suffering a severe headache afterward. In 1937, skull X-ray studies revealed intracerebral calcification. In 1943, a ventriculography was done which revealed dilated ventricles. During the past three years, the attacks have been occurring at greater intervals and with less severity. The last attack occurred in July, 1945. Repeated Wassermann, Kahn, and tuberculin tests with P.P.D. have been negative.

The ophthalmic examination at present reveals a corrected visual acuity of 20/30 in the right eye and 20/200 in the left. A quiescent, deep chorioretinitic lesion, 2 disc diameters in size, lies just nasal to the right disc. A similar lesion involves the macular area of the left eye. In the

vitreous, there are membranous residues of exudates.

The patient presents the classical clinical manifestations of toxoplasmosis; namely, intracerebral calcification, central nervous system disturbance as evidenced by convulsions, internal hydrocephalus, and bilateral chorioretinitis.

RUBEOSIS IRIDIS

DR. H. ISABELLE MCGARRY presented a 70-year-old white man who was admitted to the Illinois Eye and Ear Infirmary on November 7, 1942. He gave a history of diabetes mellitus and was taking 10 units of protamine-zinc insulin each morning. His fasting blood sugar was 190 mg./100 c.c. He gave a history of poor vision in the left eye for nine months and severe pain in the left eye for three months. Corrected vision was: R.E., 20/20; L.E., 5/200, not improved. The right disc was normal; there was a scatter of superficial and deep hemorrhages throughout the fundus and of old white exudates in the perimacular region. Gonioscopy revealed the right angle to be wide open without any newly formed vessels. The left eye showed ciliary injection, many fine, pigmented corneal precipitates, and neovascularization on the iris from the pupillary border down to the angle which was completely closed. There was a far advanced glaucomatous excavation. The tonometric readings at that time were normal in the right eye and around 55 mm. in the left.

Because of uncontrollable tension and severe pain, a cyclodiathermy was performed on the left eye on December 1, 1942. The operation was successful in that the eye became and has remained comfortable. The pressure, however, has remained elevated, and all vision has been lost. In the left eye, the typical picture of rubeosis iridis has developed gradually, with no elevation in tension, as yet.

ANGIOMATOSIS RETINAE

DR. A. A. BARAFF presented a 13-year-old white girl, recently reported here with vision of 20/20, corrected, in the right eye, and no light perception in the left eye. The right fundus showed innumerable discrete, whitish deposits in the outer retinal layers. The temporal periphery was occupied by a large, whitish mass which was studded with multiple, red, mulberry-like nodules. The vessels leading to this area were dilated and tortuous. The visual field showed a nasal constriction corresponding to the temporal lesion.

The left eye, blind for a number of years and in a state of atrophy, was enucleated several days ago. The posterior segment of this eye was not visible.

The case was presented as an angioma with retinal degeneration. As yet cerebrospinal and pancreatic findings are normal, and Dr. Bailey, of the University of Illinois Neuropsychiatric Institute, is of the opinion that the condition is confined to the eyes.

Electrocoagulation to the right temporal periphery will become advisable, if unmistakable signs of progression occur.

CHARACTERISTIC TYPES OF FILTERING SCARS AFTER CORNEO-SCLERECTOMY OR IRIS-INCLUSION OPERATIONS

DR. J. D. WALSH presented cases to show the difference between transconjunctival and subconjunctival filtration, the former occurring in blebs designated as type 1 and the latter occurring in blebs designated as type 2.

The microscopic substratum of the bleb of type 1 is a polycystic derivative of the conjunctiva, characterized by a thin external wall, thin septa between the cysts, and obliteration of the preëxisting blood vessels. Such blebs function by permitting intraocular fluid to pass from the

corneo-scleral fistula into the conjunctival sac, as can be demonstrated by means of the Seidel test. The sum total of the areas with thin external walls determines, *ceteris paribus*, the efficacy of the bleb. Such blebs are apt to form in areas where Tenon's capsule is absent and where the conjunctiva is thin. They are, therefore, the more common form of bleb after trephining operations, but may occur at the site of the conjunctival incision, or, in very old people, at sites of senile atrophy of the conjunctiva and Tenon's capsule. Corneal blebs are merely lateral extensions of conjunctival blebs.

Blebs of type 2 are less easily recognized. The conjunctival surface is not transformed. Only the deeper layers show succulence and obliteration of the preëxisting vessels. By gentle massage of the globe, the areas of type-2 blebs can be made to rise in characteristic fashion. The Seidel test is invariably negative, even after massage of the globe.

After most successful corneo-sclerectomy or iris-inclusion operations, combinations of bleb type 1 and type 2 are present. There appears to be no regular or demonstrable relationship between certain techniques of flap dissection and the type of bleb finally present.

SCIENTIFIC PROGRAM

1. The eye examination in the differential diagnosis of the disoriented patient. Benjamin Milder, Capt. (MC), A.U.S. (Published in this Journal, August, 1946.)

2. The scleral-resection (eyeball-shortening) operation. Dr. Derrick Vail. (Published in this Journal, July, 1946.)

3. Synkinetic and asynkinetic overaction of the inferior oblique muscle: Diagnosis and Treatment. Dr. George P. Guibor.

KATHERINE FERGUSON CHALKLEY, *Manuscript Editor*,
Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois; Society Proceeding to Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to Dr. F. Herbert Haessler, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising* 873 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE CHANGING SCOPE OF MEDICAL SPECIALTIES

The scope of medical specialties is constantly expanding and contracting. A brief review of the changes during the past 20 years, as compared with several other specialties, shows that ophthalmology has fared well.

In general, the layman is more interested in, and better informed about, medical problems than formerly. Magazines

and large newspapers have on their staffs writers who specialize in medical topics. The radio tells the public how to recognize cancer in the early stages; the moving pictures depict a story in which the leading character has a brain tumor; the theatre bares psychoanalysis; the advertisements tell how serious a simple head cold may be; and campaign posters tell how we can lower the incidence of venereal disease. Therefore, for the same reason that a

second-year medical student tends to become fearful lest he may have the disease to which he is introduced, the layman is more apprehensive now about his health and more frequently seeks medical advice for mere reassurance.

General surgery has been the cradle for the surgical specialties, nurturing them until they have been able to stand on their own feet as independent fields of surgical pursuit. Such has been the case with gynecology, urology, orthopedics, plastic surgery, neurosurgery, and more recently, thoracic and cancer surgery. Such will probably be the case with vascular surgery in view of the recent rapid development of new techniques in that field, such as coarctation of the aorta, portacaval anastomosis, ligation of the ductus arteriosus, and so forth.

In general medicine, the wear-and-tear diseases have increased so that the state of one's coronary arteries or the height of one's systolic blood pressure are common talk. Cardiology and allergy have emerged as specialties. The incidence of some infectious diseases has been greatly reduced and some have been practically eliminated.

Advice by the newspaper columnists, preventive medicine campaigns, school courses in hygiene including the mental phase, have all, no doubt, affected the practice of pediatrics. Complicated feeding formulas for infants have given way to more or less routine procedures so that infant feeding is no longer a major aspect of pediatrics. The use of vaccines and sera has eliminated many of the childhood diseases. Pediatrics is now more frequently concerned with the care of the premature infant and with the child's proper mental and emotional development, the aim being to prevent mental quirks, social maladjustment, or more serious nervous disturbances.

Otolaryngologists deal mostly with infection; therefore the advent of chemotherapy has narrowed their services considerably. Also, this specialty has suffered from a whispering campaign among the laymen against the treatment of sinusitis by instrumentation. The only major addition to the therapeutic repertoire of otolaryngologists is the fenestration operation.

Chemotherapy has taken the urologist out of the urethra and decreased the complications from gonorrhea. This specialty has for some unknown reason lost syphilis to the dermatologists, but its practitioners have made notable strides in the surgery of the prostate and kidney.

In neurology, less syphilis of the central nervous system is seen because the campaigns against the disease have effected better and earlier treatment. The neurosurgeons are becoming their own diagnosticians with the result that fewer neurosurgical patients pass through the hands of the neurologist. The neurologists are concerning themselves increasingly with functional and psychosomatic disorders, diseases emanating from dysfunction of the endocrines, and from allergy. Their therapeutic armamentarium has always been sparse but the electric shock treatment is quite promising.

In ophthalmology during the past two decades, we have extended our frontiers and lost little ground. The most notable addition to our surgery is the operation for detachment of the retina. The corneal transplant operation is no longer in the experimental field but is now included in the regular surgical repertoire. A dacryocystectomy is passé and has been replaced by the dacryocystorhinostomy. After some contention between the rhinologist and the ophthalmologist, this operation has now been incorporated in the domain of ophthalmology. A similar tug-of-war

has been waged over plastic work in the region of the eye with the result that ophthalmology has retained a fair portion of it. The subjects of aniseikonia and orthoptics have been developed and applied. The recognition of keratoconjunctivitis sicca as a part of the Sjögren syndrome, the appreciation of the roles toxoplasmosis, sarcoid, and brucellosis play in ophthalmology are all steps forward, and there are many other noteworthy advances which could be mentioned.

The changes in medicine occur so gradually and over such a long period that an assessment is necessary to appreciate them. Even this cursory glance at the changes during the past 20 years shows that there is a constant shifting in the scope of the specialties and that not one is static.

Algernon B. Reese.

MISGIVINGS AS TO THE TECHNIQUE OF CATARACT OPERATIONS

There is ample room for doubt as to choice of technique in performance of the operation for cataract. It is entirely reasonable to assume that various types of cataract call for different methods of approach. On the other hand, very few are the operators who throughout their professional career continue to employ exactly the methods taught to them during their early training.

That this is not merely a sign of progress from an inferior method to a better one is fairly well demonstrated by the fact that at any given period any selected group of eminent ophthalmic surgeons will be found to vary in their choice of technique. It is also significant that the statistical results recorded by the members of such a group, and the complica-

tions experienced, will differ much less widely than their choice of methods.

No ophthalmic surgeon, however eminent and experienced, is immune from failure in the results obtained by cataract operation. This is one reason why the individual operator is usually found ready to try a number of different methods in the course of his career.

Here and there a well-known eye surgeon may be found disposed to doubt whether real advance in cataract surgery has been achieved in the past half or three quarters of a century. One of these skeptics is Manuel Rivas Cherif, formerly of Madrid, Spain, but now domiciled in Mexico ("Voluntary complications in the operation for cataract." *Archivos Médicos Mexicanos*, 1946, volume 4, February, page 3). The author means precisely what he says in speaking of "voluntary" complications, for he is convinced that many of the so-called improvements in cataract technique invite trouble instead of avoiding it.

In his 34-page paper Rivas Cherif finds fault, one after the other, with many of our boasted developments in technique. From simple, he says, the cataract operation has become complicated, often to the detriment rather than to the benefit of the patient. He decries fashion in ocular surgery or a desire to adopt the new for fear of being thought antiquated, urging that too often the so-called new is merely a return to an earlier method. Unless, he says, we are sure that the patient gains, it is undesirable to occupy half an hour over an operation that ought to last five minutes at most.

As an example of the author's judgment may be mentioned his contention that in the great majority of cases it is adequate to use contact anesthesia with instillations of 4-percent cocaine solution, which he has found effective even where iridectomy

was necessary. Objections to retrobulbar anesthesia include inability of the patient to coöperate in rotation of the eye and the possibility of causing serious orbital hemorrhage or of puncturing the optic nerve. Hypotony induced by retrobulbar anesthesia, though welcomed by some surgeons, is blamed by Rivas Cherif as a serious inconvenience in the performance of extracapsular extraction. It is also, he believes, to be held responsible for the frequent occurrence of detachment of the choroid, which he regards as far more inimical to the future of the eye than is usually admitted. Akinesia he regards as not indispensable, and as unnecessarily distressing for the average patient, without possessing adequately compensating advantages. Only in very rare cases would he use canthotomy.

Rivas Cherif points out that although we all agree on the importance of a correct incision for success of the operation, unfortunately our unanimity is solely one of principle, because after having performed large, small, and medium incisions, in every conceivable part of the cornea and of the anterior sclerotic, we are still discussing this technical detail.

In the early part of the present century, a number of European surgeons experimented with the use of either one or two lance keratomes for the limbal incision. In 1928, Aubaret employed two keratomes, one in each hand, entering the eye with both at the same time; and when the two blades met he withdrew one keratome and divided the remaining corneal bridge.

Rivas Cherif still prefers the limbal incision of two fifths of the corneal circumference, and omits the conjunctival flap because of a belief that it adds to the danger of hemorrhage. He points out that an incision situated on the limbus is farther from the root of the iris than from the border of the fully dilated pupil, and

he argues that with such an incision iris prolapse is rendered less possible and iridectomy less necessary. He clings to the use of the Graefe knife for the section, as quicker and more accurate than keratome and scissors. He is, however, an adherent of the sclerocorneal suture, which he regards as having substantial advantage with practically no inconvenience.

It is natural that Rivas Cherif should express himself as to the choice between the intracapsular and the extracapsular method. He is manifestly more or less partial to the extracapsular. He states his agreement with the opinion of Van Lint that mature or almost mature cataract should be extracted without the capsule, that the unripe cataract should be extracted intracapsularly in patients whose physiologic age is between 60 and 70 years, that patients less than 60 years of age should be dealt with by the extracapsular method because the more resistant zonule renders the intracapsular dangerous, and that the extracapsular should be used after 70 because the lens masses surrounding the nucleus are not sufficient to produce secondary cataract.

Yet most of us have seen a good many exceptions to all of these rules. In spite of the downright assertion of the late T. Harrison Butler, a year or so ago, that the intracapsular was far more dangerous than any other type because of the heavy pressure he had found necessary to deliver the lens (*British Journal of Ophthalmology*, 1943, volume 27, November, page 495), it is probable that most operators of experience now undertake the intracapsular method in the majority of their cases, and regard it as generally to be preferred to the extracapsular.

Rivas Cherif's assertion that, from the day after the extraction, those operated upon by the extracapsular show much less ocular redness than those operated

upon by the intracapsular method certainly does not agree with the experience of most United States surgeons who widely practice the latter. Can it be that some Mexican surgeons (like Harrison Butler in his brief experience) are accustomed to use more pressure in intracapsular extraction than is usual among North American operators, instead of relying largely upon slow, gentle traction with the capsule forceps?

Another opinion by Rivas Cherif which seems to come down to us from the past is that "always when there is no indication to the contrary the cataract should be allowed to reach complete maturity." How many of our cataract patients lack such an "indication to the contrary"? Surely the vast majority of them, long before the worse eye reaches full maturity, are subjected to serious inconvenience as to the use of the better eye. A most important benefit conferred by the popularity of the intracapsular operation is avoidance of the long twilight period involved in waiting for complete maturity.

Earlier details of technique are forgotten, to be later revived, retried, sometimes reapproved, but seldom in the original combinations. It is well for us all, and especially for the novice, to realize that the methods now in use may not be the only ones acceptable or successful, but are just as likely to undergo further change as those which, widely used many years ago, have been swept into relative oblivion.

W. H. Crisp.

RADIOACTIVE ISOTOPES

One fact proved to us by wartime research programs as, for instance, that of the National Research Defense Committee and the Office of Scientific Research and Development, was that certain victories in investigative work can be

achieved in a vastly accelerated manner by coöperation between research scientists. Duplication of effort is reduced to a minimum, and strength and encouragement lends impetus to the whole performance when there is coördination of activity of men carrying out research on any matter of common interest. An example of the carry-over of this spirit of coördination of knowledge and essential materials for a finer type of research is the program of the Radioactive Isotope Committee of the Massachusetts General Hospital of which the Massachusetts Eye and Ear Infirmary is a part. Other research groups will do well to follow the plan of this committee, seeking consultation from the best qualified members of their respective scientific communities. Physicists from Harvard and the Massachusetts Institute of Technology serve as consultants for the radioactive isotope project at the Harvard Medical School, radioactive materials being obtained largely from the Massachusetts Institute of Technology cyclotron.

A talk given by Dr. Francis D. Moore at the Massachusetts General Hospital and abstracted in *The News* for August, offers a concise discourse on "The Application of Isotopes to Surgical Research." This abstract read, in part, as follows:

"The word 'isotope' means 'same place' or 'same phase' and denotes an element occupying the same position chemically as another element but differing from it in weight. Most of the common elements of the earth's surface are mixtures of various isotopes and, of late, the application to many problems of isotope production and detection has expanded rapidly and in many fields, ranging from determinations in submicroscopic life up to 'atomic' explosions in the air over Japan.

"The basic pattern for biologic research with radioactive isotopes was laid many

years ago when Continental workers studied some problems relative to the biology of lead, using radium as a 'tracer.' The possibilities of such methods remained limited and application to a wide variety of biologic problems was impossible until the last decade when, with the development of the cyclotron, a host of radioactive isotopes of common, biologically important elements became available. A tremendous upsurge in this type of research has since taken place, and for a few years it was almost a monthly, and even in some cases a daily, occurrence for physicists to discover a new isotope! As each element in the periodic table was bombarded with deuterons in the cyclotron, a study of the reaction products yielded many hitherto unknown isotopes of previously known elements.

"Many of these substances were radioactive and by their radioactive emissions announced their presence in the tissues, body fluids, and in the test tube.

"In its peculiar organ specificity, iodine is almost unique among the body's elements. Furthermore, the radioactive isotopes of iodine emit gamma radiation which penetrates the tissues of the patient and can be detected externally with a Geiger counter. This fortunate combination of circumstances plus a convenient half-life gave to the iodine work a peculiar clarity and interest which attracted wide attention and is quoted in most of the articles one may read on the biologic application of isotopes. This work has recently blossomed into the treatment of thyrotoxicosis with radioactive iodine and in the application of these methods to the diagnosis and treatment of thyroid tumors as well as the further elucidation of thyroid physiology.

"In 1941, under the aegis of Dr. Aub and his group, work was commenced on radioactive colloids, making some of the

common colloidal di-azo dyes radioactive by synthesis into the molecule of two atoms of radiobromine. This work was of interest because these dyes concentrate in abscesses and tumors and because one might hope by such means to diagnose abscesses from outside the patient by use of a Geiger counter or to treat tumors by injecting the radioactive dye. This work was done under considerable difficulty because of the very small amounts of radioactive substances which were available at that time. Now, with the great expansion in radioactivity research engendered by the atomic bomb and the development of the 'chain-reacting pile' as a means of producing radioactivity, these problems are being reopened and reinvestigated by workers in many places, and it is with considerable gratification that we now find workers in Philadelphia and in Berkeley, California, reinvestigating these problems with the higher amounts of radioactivity obtained from the atomic bomb plants.

"In 1942 the interests of the Surgical Service shifted to the study of water balance in burns, a problem encouraged by the government OSRD contracts, and pursued throughout the war. Up to the present time, research has been carried out on the Surgical Service employing radioactive isotopes of sodium, chlorine, bromine, potassium, iodine, phosphorus, iron, and hydrogen. The end-point detection involved in these research problems (with the exception of iron) have been carried out by our own investigators in the surgical laboratories; the radioactive materials have been obtained largely from the Massachusetts Institute of Technology cyclotron.

"The development of the atomic bomb has attracted wide public attention to the problems of nuclear physics and has made 'neutron' a household word. The develop-

ments relative to the bomb have also given rise to much interest in the research world, and we read daily in the papers of thousands of dollars being poured into work with radioactive isotopes, especially as applied to the problems of malignancy. There are many rewards to be found in this field, and many new discoveries will be made. Some will doubtless apply to the field of malignancy, but many others will be useful and important in everyday problems of the physician and surgeon.

"The types of research problems which can be investigated with isotopes can be divided into several categories:

1. "*Membrane equilibrium and permeability.* This is the basic contribution of radioactive isotopes to research. Reaction rates, permeability rates, equilibrium ratios and cell permeability can be studied with radioactive isotopes in a fashion that is impossible by other means. In this way we have studied capillary permeability, red-cell permeability, the changes in permeability of skin cells to sodium after burns, and from methods falling into this category, we may look to the future to find many answers to questions concerning water balance, electrolyte administration and pre- and post-operative care. The central problem in this therapeutic field at the present moment might be described in a few words as 'potassium deficit.' Is there a need for potassium in parenteral fluid therapy? If so, how great is the need and how does one know when the need has been satisfied? These and related problems can best be solved by the judicious use of isotopes." (Among the contributions in this category of particular interest to ophthalmologists is the work of Cogan, Kinsey, and Grant (1942) on the use of heavy water, deuterium oxide (D_2O) as a tracer for ordinary water in measuring the movement of water into and out of the aqueous, as well

as other contributions they have made using radioactive isotopes.)

2. "*'Tracing' elements or molecules in the body.* By the use of radioactive substances the distribution and reactions of various organic and inorganic compounds can be traced in the body. The classic work of Schoenheimer and Rittenberg, in which heavy stable isotopes rather than radioactive substances were used, is an example of studies in this field which have clinical significance. From their work, we find that all the protein in the body is in a constant state of flux and equilibrium, and that there is no such thing as storage or inert protein. By similar methods, we may in the future discover the site of the formation or action of various hormones, the distribution of nutritional essentials in the body, the fate of drugs and cancer-forming compounds.

3. "*The location of certain elements or molecular configurations from outside patients.* The use of iodine in this connection has already been mentioned. After iodine is given to the patient, a Geiger counter can be placed over the thyroid and the amount taken up by the thyroid can be roughly estimated. Work on the detection of abscesses has also been mentioned. Future work in this field holds much of interest relative to circulatory physiology, circulatory velocity, the effect of certain types of sympathetic surgery on circulation in various areas in the body, and other studies. In using this technique, one must always bear in mind the fallacies and pitfalls of externally placed counter measurements as they are affected by various thicknesses of tissue and other biologic factors.

4. "*The measurement of body 'areas.'* By use of isotopes one can measure with some degree of accuracy the exact amount of certain areas of body fluid in the body and the amounts of certain elements

present. This type of work is at present the main concern of the Department of Surgery as it relates to isotope investigation. We can measure the extra-cellular space with sodium and the total body water with deuterium. We can measure the total body potassium with radioactive potassium, and we can measure the degree of potassium utilization by the development of a potassium tolerance test that depends upon the urinary excretion of a measured dose of radiopotassium. In this way a chemical 'dissection' of the human body can be carried out on the living patient. Previously, a complicated quantitative analysis of a human cadaver would be the only way of getting the same data.

5. "*Treatment.* The treatment of various sorts of radio-sensitive diseases with radioactive isotopes is an obvious application of these materials. Thyrotoxicosis has been mentioned, as has thyroid tumor. Radiophosphorus has been developed as a means of treating certain types of blood dyscrasia and polycythemia vera. The future of this field lies not so much in the further application of inorganic ions to the treatment of tumors as it does in the discovery of specific organic chemical configurations which are taken up in tumor tissue and which can be rendered radioactive so as to administer selective internal radiation to tumors.

"One cannot discuss this field without stressing the hazards of radiation, and a committee has recently been formed in this hospital to review isotope research being carried out here with the hope of avoiding such hazards. The purpose of this committee is not only to correlate work and avoid unnecessary duplication or expenditure, but also to safeguard the patients and the workers from radiation which may be dangerous. Five years ago when one or two millicuries of a radioactive isotope was regarded as mammoth

production, dangers to the worker were not as great as they are now when the cyclotron can make 170 to 200 millicuries of radiosodium in a few hours. Such large amounts of activity can be dangerous to both worker and patient; realization of these hazards must be brought home to all those involved, and proper precautions taken.

"Future trends in this field will be watched with interest by physicians and surgeons alike. It is essentially a collaborative type of investigation and has always involved coöperation at least between the physician and the physicist. Now we must extend this coöperation to the various services in our hospital so that the knowledge and skill of the Medical Service, Pediatric Service, Surgical Service, and others can be brought to bear upon problems that concern us all—problems to be solved by the tools of the physicist."

I believe this abstract, as quoted above, merits our serious attention, for only by a coördinated approach, strengthened by the availability of experts in the fundamental branches of science—an approach such as is exemplified in the recommendations of the Radioactive Isotope Committee of the Harvard Medical School—can the majority of significant eye problems be solved.

S. Rodman Irvine.

OBITUARY

ROBERT VON DER HEYDT

(1875-1946)

The death of Dr. Robert Von der Heydt on September 18, 1946, was a great loss to the profession of ophthalmology and the loss of a valued and beloved member.

Dr. Von der Heydt had come to be

well-known and appreciated by a large number of men in the United States, principally because of his leadership in developing the use of the slitlamp. His earliest interest was in the mechanical side of ophthalmology, for he was a true craftsman and able to improve upon almost any optical instrument that came

ROBERT VON DER HEYDT

into his hands. Soon, however, the clinical interest dominated, and he studied biomicroscopy with Vogt in Zurich and with Fuchs and others and translated Vogt's first Atlas into English. He taught groups in post-graduate courses, gave courses almost yearly at the Academy and at the Illinois Eye and Ear Infirmary, and trained numerous individuals in this branch. Many of us went to him for advice and help, for his generosity in the sharing of knowledge and his expenditure of time for others were unlimited. He was always coöperative and kind as a consultant. Many valued his help and friendship.

Those attending the meetings came to know him for his color slides of external and fundus diseases, for he adapted ko-

dachrome to both when most men were still using black and white. He was also among the pioneers in contact-lens fittings.

Dr. Von der Heydt was born in Wiesbaden, Germany, in 1875, and came to this country at the age of six. He received his education in the Chicago schools and was sent to Germany at the age of 16. In his early manhood, he studied watch making and always carried a watch he himself had made. Working with his father on his return from Germany, it became his duty to keep the large clock at Rush Medical College in good order. It was here that he began to wish for a medical education and for a teaching position at Rush. This wish was fulfilled through his own efforts. He received his medical degree at the University of Illinois in 1903 and practiced ophthalmology in Chicago until his death.

Dr. Von der Heydt was Professor of Ophthalmology at the Chicago College of Medicine and Surgery from 1909 to 1917, Associate Professor at Rush Medical College from 1926 to 1940, and at the University of Illinois from 1940 to 1943. From 1943 until his death, he was Professor Emeritus of Ophthalmology at the University. He was ophthalmologist at the Illinois Charitable Eye and Ear Infirmary from 1905 to 1943 and was attending ophthalmologist at Michael Reese Hospital and West Suburban Hospital.

Dr. Von der Heydt was a member of the American Ophthalmological Society to which he was elected in 1930. He was a member of the American Medical Association and of the Academy of Ophthalmology and Otolaryngology, and was past president of the Chicago Ophthalmological Society.

Dr. Von der Heydt is survived by his wife, Edith Richardson Von der Heydt, and two daughters, Mrs. Franklin Briston and Harriett Von der Heydt.

E. B. Fowler.

BOOK REVIEWS

DISEASES OF THE RETINA. By Herman Elwyn, M.D. Clothbound, 587 pages, 170 illustrations, 19 in color. Philadelphia, The Blakiston Company, 1946. Price, \$10.00.

Dr. Herman Elwyn, senior assistant surgeon of the New York Eye and Ear Infirmary, divides his book, "Diseases of the Retina," into eight parts. Each part is a classification or category of the subject matter he presents, and these categories are:

Part 1, Diseases of retina resulting from disturbances in circulation; Part 2, Diseases of retina resulting from vascular malformation; Part 3, Degenerative diseases of retina on a hereditary basis; Part 4, Inflammatory diseases of retina; Part 5, Tumors of retina; Part 6, Diseases of retina leading to retinal detachment; Part 7, Developmental anomalies of retina; Part 8, Radiation injuries of retina.

The division of the subject matter of this book under these arbitrary headings was disappointing to this reviewer. It has resulted in a somewhat scattered classification and does not present the material "for students, practitioners, and ophthalmologists," as the author states was his intention, but presents it only for ophthalmologists.

In view of present-day discussions concerning the classification of fundus disease (and it would seem this should be a must in a treatise as complete as this book), one would expect the most recent classifications to be mentioned. This reviewer is aware, however, that classifications as such are merely a means to an end and not the means to further research in a subject which is so important in an age of preventative medicine.

Dr. Elwyn does bring several "new" diseases of the fundus to the attention of

the reader, diseases which, I believe, are not to be found in other texts; such as, fundus findings in endocarditis and the blood dyscrasias.

The discussion of the pathogenesis and pathology of each disease presented in this book is both well-written and well-documented, and Dr. Elwyn has been careful to bring his terminology up-to-date. The bibliographies at the end of each chapter are, however, not at all complete.

All in all, "Diseases of the Retina" is a readable book, well-written, well-illustrated, and set in exceptionally legible type that is easy on the eyes. It should find a place in every ophthalmic library.

Nathan K. Lazar.

EYE HEALTH—A TEACHING HANDBOOK FOR NURSES. Prepared and published by the National Society for the Prevention of Blindness, Inc., 1790 Broadway, New York 19, New York. Paper bound, 108 pages, 5 figures, bibliography, index. Price, \$0.60.

This is a well-arranged and useful manual, prepared particularly for the school, public health, or industrial nurse. It is surprisingly broad of scope, although of necessity compact, and gives to its reader more than an introduction to the eye and its use or abuse. Its chapters deal in part with the organs of vision, the seeing process, making the best use of the eyes, "screening" eye examinations, the eyes in childhood, eye health problems in adult life, eye safety, first aid and follow-up for eye injuries, and the teaching of eye health.

It is well and clearly written in terse sentences and should be easily understood. It is recommended not only to those for whom it is designed, but also to lay people interested in eyes and eye health, of whom there are many.

Derrick Vail.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |

1

GENERAL METHODS OF DIAGNOSIS

Almeida, A. de. Examination of the ocular fundus in children, as bearing upon diagnosis. *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 76-85.

The author discusses the relationship of ophthalmology to pediatrics, and reports a personal case of hemorrhage of the newborn, with observations of a year of investigation in the Maternity Hospital of Campinas. The author's review touches briefly on cerebral hemorrhage and hematoma, tumors and meningitis, phacomatoses, acute illnesses, and avitaminoses. (4 figures.)

W. H. Crisp.

Casanovas, J. *Radiographic methods for the localization of foreign bodies of the visual apparatus*. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, May, pp. 327-337.

After reviewing several methods of localizing ocular foreign bodies the author presents the following method. A silver ring of 0.5 mm. thick and 11 mm. in diameter is sutured to the limbus at three points equidistant from

each other. A binocular bandage is put on and frontal and lateral X-ray pictures are taken making allowance for the upward and outward rotation of the closed eye. Preliminary fluoroscopy aids in the orientation. If the radiograph has been taken properly the ring will appear perfectly round in the frontal view and as a straight line in the lateral view. A diagram is drawn consisting of two concentric circles, one of 11-mm. diameter corresponding to the limbus and the other 24 mm. in diameter corresponding to the diameter of the globe. Another diagram is drawn that consists of a 25-mm. circle, the circumference of which cuts the extremities of the 11-mm. vertical line that corresponds to the lateral view of the ring. By combining the two lines an accurate localization of the foreign body is obtained. For bone-free radiography the method of Vogt is used with the modification that a broad spatula is used to carry the dental film.

J. Wesley McKinney.

Freitas, Orlando de. *Bacterioscopic examinations of conjunctival secretions*. *Arquivos do Instituto Penido*

Burnier, 1945, v. 7, Dec., pp. 179-195. (See section 5, conjunctiva.)

Goldmann, H. A self-registering bowl perimeter with projection of the target. *Ophthalmologica*, 1945, v. 109, Feb.-Mar., pp. 71-79.

The author, in cooperation with the firm of Haag-Streit in Berne, Switzerland, constructed a bowl perimeter which fulfills all the conditions necessary for exact quantitative perimetry. Objects of various size and color and always exactly of the same reproducible degree of contrast are projected by a movable optical system onto the field of the perimeter bowl. The optical system is attached to the bowl. The movements of the projected target point are controlled by a manipulator behind the perimeter bowl. These movements can be executed in any direction, not only radially as in the usual arc perimeter. Exact fixation by the patient's eye and its control by the examiner is safeguarded by special means.

Max Hirschfelder.

Guerry, III, Du Pont. Recent advances in the diagnosis and treatment of diseases of the external eye. *Virginia M. Monthly*, 1946, v. 73, April, pp. 173-178.

This excellent paper discusses the diagnosis and treatment of external eye diseases such as blepharo-conjunctivitis, chalazion, trichiasis, molluscum nodula, herpes zoster ophthalmicus, metastatic dacryoadenitis, gonorrhea, vernal catarrh, trachoma, Parinaud's syndrome, corneal ulcers, and dendritic ulcers.

I. E. Gaynon.

2

THERAPEUTICS AND OPERATIONS

Bien, Morris. General anesthesia in ophthalmic surgery. *Amer. Jour.*

Ophth., 1946, v. 29, Sept., pp. 1119-1121.

Brown, C. A. Penicillin in ophthalmology. *Brit. Jour. Ophth.*, 1946, v. 30, March, pp. 146-167.

In this comprehensive article the author discusses the bacteriologic properties of penicillin as regards experimental data on the penetration of the drug in the normal and infected eye, and the control of infection. Clinical evidence of its action in 125 cases of infection leads him to conclude that penicillin is the ideal drug for combatting bacterial infections of the eye. It is harmless to ocular tissues and lethal to most bacteria that attack the eye. It acts equally well when applied topically for external infection and when injected into aqueous or vitreous for intraocular infection. (36 references.)

Morris Kaplan.

Fraser, I. C. and Scott, A. A. B. Penicillin treatment of ocular inflammation. *Brit. Jour. Ophth.*, 1946, v. 30, March, pp. 168-176.

The details of 38 cases of blepharitis and conjunctivitis in the treatment of which penicillin was used topically are presented in tabular form. The solution used contained 500 units per c.c. and was instilled every four hours. In eight cases lamellae of penicillin containing 180 or 100 units were used four-hourly. No other treatment was employed and the results were most striking. Blepharitis, that had existed for 20 years was cured completely in a few days. Two patients with Eales' disease were not benefited by penicillin.

Morris Kaplan.

Goldman, H. The basis of exact perimetry. *Ophthalmologica*, 1945, v. 109, Feb.-March, pp. 57-70.

The author investigated with mathematical exactness the different variables which are of importance in exact perimetry and reached the following conclusions. To perform exact relative perimetry with colourless objects adaptation equilibrium must be established, the contrast between object and perimetry background must remain constant, and the basic illumination must not change greatly. Under such conditions quantitative relations may be found between perimeter objects of varying size. A quantitative comparison of the sensitivity of individual retinal points becomes possible on the basis of perimetric data gained with objects of different size. One can characterize each point on the retina not only through its differential sensitivity, but also through its cumulative power ("Summationsleistung") for objects of different size. The cumulative power of normal retinal points may be considered constant over wide areas of the visual field. The limits of the constancy were determined in the study and it was found that distinct vision seems to decrease this cumulative power, while dark adaptation seems to increase it. Perimetry with white objects depends on the sharpness of vision with which these objects are seen. Errors of refraction, presbyopia, and cloudy media reduce the black-white visual field considerably. Patients with refractive errors should wear their glasses during perimetry. When the media are cloudy, the results of perimetry with white targets can only be used with caution in the diagnosis of disturbances in the retina or optic nerve. Colour perimetry seems to be less influenced by such blurred images.

Max Hirschfelder.

Lech Junior. Vanadium in ocular syphilis. *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 204-211.

The author's statistics suggest a striking advantage from the use of potassium and sodium tartrovanadate. As compared with other specific drugs, the mean time of recovery fell from four to two months, the average improvement in sight in four months was from 0.17 to 0.38. After six months of vanadium treatment, 63 percent of the patients showed vision improved to 0.5 or better. (3 graphs.) W. H. Crisp.

Mann, Ida. Intraocular use of penicillin. *Brit. Jour. Ophth.*, 1946, v. 30, March, pp. 134-146.

Experiments were done on rabbits to determine the effects of intraocular injection of penicillin in various concentrations and to determine the concentrations remaining at known intervals of time after injection. Immediately after the injection of 200 to 1500 units into the aqueous of 16 eyes a coagulum of many fine particles that completely filled the anterior chamber was observed with the slit lamp. This disappeared after several hours. A slight corneal reaction disappeared in several days. The severity of reaction did not vary with the concentration of the drug.

Injection into the vitreous produced a local opacity immediately, which eventually involved the entire vitreous. On the fifth to seventh day a severe exudative chorioretinitis appeared and progressed rapidly to complete atrophy and blindness. In four to five weeks a degeneration of the iris was noted and was accompanied by cataract in some eyes. Microscopically most of the tissues were unrecognizable. The retina, choroid, and optic nerve became fibrous.

Into six eyes chemically pure penicillin was injected with entirely different results. After a mild local reaction the fundus became entirely normal in three weeks in all eyes. The reactions in the other group were doubtlessly due to impurities in the drug.

In the second group of experiments it was found that no penicillin remained in the aqueous and vitreous one hour after the intravenous injection of 5,000 units. After injection directly into these areas the drug persisted in beneficial amounts for six hours. It was found to diffuse from the vitreous into the aqueous.

Case reports of 29 eyes treated with injections are presented. The solutions used contained from 1,000 to 50,000 units in 0.25 c.c. of fluid which is the ideal volume for injection. Results were considerably better than could be expected from any other form of treatment.

Missiroli, Giuseppe. The frequency of various types of pneumococcus in ocular affections and their respective sensitivity to sulfamids. *Boll. d'Ocul.*, 1944, v. 23, July-Sept., pp. 166-194.

The author made a systematic study of the distribution of the various types of pneumococcus according to modern immunologic classification. He examined 145 strains of the coccus isolated from eyes with conjunctivitis, dacryocystitis, and serpiginous corneal ulcer. Twenty-three types predominated. In a second series the author studied the sensitivity of pneumococci from sulfamido-pyridinic preparations. The types of organism differed in resistance to sulfamids. (Bibliography.)

Melchior Lombardo.

Parry, T. G. W. and Laszlo, G. C. Thrombin technic in ophthalmic sur-

gery. *Brit. Jour. Ophth.*, 1946, v. 30, March, pp. 176-178.

The authors present a preliminary report on the use of commercial thrombin (P-D) thrombin topical) as a healing agent in eye surgery. In cataract extraction they placed this thrombin paste under a large conjunctival flap and used no sutures. In squint surgery they placed the paste on Tenon's capsule or under the conjunctiva after suturing the muscles. Results were most promising. The thrombin also acted as an efficient hemostatic.

Morris Kaplan.

Scuderi, G. The action of sympamina (beta-phenyl-isopropylamine). *Rassegna Ital. d'Ottal.*, 1946, v. 15, March-Apr., pp. 94-106.

Sympamina is a synthetic drug, structurally quite similar to ephedrine. The chemistry is explained and the literature reviewed. Dropped into the eye, sympamina produces moderate mydriasis, which begins in ten minutes, has no effect upon the ocular tension, produces a contralateral miosis, and has a synergistic action with cocaine, atropine, and homatropine. The action is somewhat unpredictable and varies in different eyes. The rate of absorption through the cornea was found to vary considerably. The action of this drug varies with the pH. The preparation seems to be very similar in its effect to the other drugs of the adrenin group.

Eugene M. Blake.

3

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Amsler, M. and Klauser, O. Measurement of high values of refraction in keratoconus. *Ophthalmologica*, 1945, v. 110, July-Aug., pp. 29-33.

The extreme values of refraction

found in conical corneas are not suitable for measurement by the ordinary Javal ophthalmometer. With the aid of the photokeratoscope of Amsler the reflex image of a disc of Placido was photographed on a series of steel balls of known curvatures. The pictures obtained can be compared with the ones obtained from the reflex image of conical corneas. In this way corneal curvature can be estimated fairly exactly. The authors offered a complete scale of steel-ball-reflex images for this purpose.

Max Hirschfelder.

Angius, T. **Experimental research on twilight vision.** (Part 2.) *Rassegna Ital. d'Ottal.*, 1946, v. 15, May-June, pp. 182-190.

Since vitamin A is essential to the formation of rhodopsin, Angius felt that there might be an increase of this substance in the periphery of the retina. The Birch-Hirschfeld adaptometer was used in the experiments. The conclusions reached were: (1) that vitamin A has no clear action in the perception of form in the peripheral field in normal subjects who are not fatigued; (2) that it has a favorable effect upon subjects exposed to intense light and fatigue; (3) that it brings about an increase in the perception of light at the periphery of the retina, and (4) that it has no appreciable action on normal individuals exposed to dazzling, if not fatigued.

Eugene M. Blake.

Bender, M. **Polyopia and monocular diplopia of cerebral origin.** *Arch. Neurol. and Psychiat.*, v. 54, Nov.-Dec., p. 323.

Cases of objective and subjective disturbances in the visual fields with associated defects in mechanisms of fixation are described. The patients had either

monocular diplopia or polyopia or both, and some of them also had symptoms of spatial disorientation. It is concluded that the rapid and involuntary movements of the eyes produced by faulty fixation tend to stimulate, simultaneously, the original macula and any new maculas which may have been formed as a result of impairment of vision.

Theodore M. Shapira.

Bender, M. B. and Teuber, H. **Phenomena of fluctuation, extinction, and completion in visual perception.** *Arch. Neurol. and Psychiat.*, 1946, v. 55, June, pp. 627-658.

In three illustrative cases of disturbances of visual fields with scotoma of varying extent and density, phenomena of fluctuation, extinction, and completion were observed.

The three phenomena appear to be related to each other. Fluctuation was characteristic in all cases, particularly on prolonged exposure. Extinction seemed to represent a more extreme form of fluctuation; since it occurred readily in areas which were otherwise characterized by fluctuation. In these areas extinction could be demonstrated frequently on double simultaneous stimulation. With rapid tachistoscopic exposure of patterns, the defects in the visual fields seemed to be reduced in their extent in all three cases. This fact suggested that these field defects (though produced by circumscribed lesions) were a result of processes of extinction rather than signs of a permanent loss in function. For that reason, rapid tachistoscopic exposure would prevent extinction and produce the appearance of completion. Completion could thus be understood as a simple absence of "extinction."

It should be considered that comple-

tion, and other phenomena described in this communication, are not confined to visual and cutaneous perception. Taken in a wider sense, they can be found to pervade the so called higher functions, such as processes of memory and thought. Studies in reminiscence are a case in point. The principles of function which are signalized in the phenomena of fluctuation, extinction, and completion may thus have general application. Theodore M. Shapira.

Bliss, A. F. **The chemistry of daylight vision.** *Jour. Gen. Physiol.*, 1946, v. 29, May 20, pp. 277-297.

Rhodopsin, a red substance obtained from the rods and known as visual purple, is the basis of scotopic vision. It has physical and chemical properties that suggest that it is a conjugated protein which liberates a prosthetic group related to vitamin A as a consequence of the absorption of light. In the living eye, dark adaptation results in the removal of vitamin A and the regeneration of visual purple. In this study of the chemistry of cone vision, Wald's discovery of iodopsin, a photosensitive cone pigment in the retina of the chicken was verified. Iodopsin resembles rhodopsin in its chemical properties but is considerably more labile. (6 figures, 5 tables, references.)

Bennett W. Muir.

Bliss, A. F. **Photolytic lipids from visual pigments.** *Jour. of Gen. Physiol.*, 1946, v. 29, May 20, pp. 299-304.

A method is described for the preservation of iodopsin, the labile photopigment of daylight vision, by freeze drying in vacuo. The lipids released by the action of light on rhodopsin and iodopsin are found to be similar and to possess a labile absorption spectrum in

chloroform, with a rising peak at about 390 m μ and a declining peak in the region of 470 m μ . After the change is complete the absorption spectrum closely resembles that of retinene. (2 figures, references.)

Bennett W. Muir.

Carlevaro, G. **An anomaly of refraction.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, May-June, pp. 202-206.

The condition discussed by the author has been variously called asymmetry or decentration, bi-astigmatism, keratoconus frusto, and irregular astigmatism of the lens. Carlevaro modified the keratoscope of Gullstrand for the study of such cases of structural irregularity and he reviews the various theories offered by different observers. He concludes that the correct denomination is asymmetry and decentration.

Eugene M. Blake.

Crisp, W. H. **A device for group demonstration of astigmatism tests.** *Amer. Jour. Ophth.*, 1946, v. 29, Sept., pp. 1094-1098. (1 figure, discussion.)

Hecht, S., Hendley, C., Frank, S., Haig, C. **Anoxia and brightness discrimination.** *Jour. Gen. Physiol.*, 1946, v. 29, May 20, pp. 335-351.

Seven men and one woman, all 17 to 25 years of age, were placed under experimental physiologic conditions corresponding to variations in altitude between sea level and 17,000 feet. Using controlled brightness, the brightness discrimination was tested repeatedly with a Landolt broken ring test object. It was noted that deterioration of contrast discrimination is definite at 8,000 feet and is marked at 15,000 feet. A given increase in altitude results in a greater impairment in contrast recogni-

tion at high altitudes than at lower ones. Although the deterioration in brightness discrimination occurs at all three light intensities tested, the effect decreased as the illumination increased. Cone and rod thresholds are affected equally by low oxygen concentration. It is probable that the retina itself, rather than the central nervous system, may be the seat of the anoxic changes. (6 figures, 4 tables, references.)

Bennett W. Muir.

Hunt, G. D. **Correcting amblyopic eyes.** *The Optician*, 1946, v. 111, July 12, pp. 476-477.

Too many amblyopic eyes have been fitted with plano or balance lenses. In presbyopic patients the corrected amblyopic eye often makes an effective contribution to the work of the dominant eye.

I. E. Gaynon.

McKay-Ferguson, Olig. **The development of the theory of light.** *The Optician*, 1946, v. 111, July 5, pp. 453-454.

Descartes first definitely stated that light takes the form of minute fragments of matter traveling from object to image at high velocity. Newton discovered the composite nature of white light. Huygens' wave theory explained the phenomena of reflection and refraction. Fresnel remedied the flaw in Huygens' theory by providing a satisfactory account of the propagation of light in straight lines and explained interference and diffraction. Maxwell then brought out the electromagnetic theory, which was followed by the electron theory of Lorentz. The quantum theory as explained by Einstein, according to which the absorption and emission of energy is a discontinuous process, takes us back to the corpuscular theory.

I. E. Gaynon.

McKay-Ferguson, Olig. **Entopic phenomena.** *The Optician*, 1946, v. 111, July 19, pp. 495-499.

Entopic phenomena include all visual phenomena that arise from stimuli within the eye. Retinal blood vessels lie in front of the rod and cone layer. If light falls on the retina in such a way as to cast a shadow, the outlines of the blood vessels are observed. The spot phenomenon can probably be ascribed to the leucocytes, inasmuch as the red blood cells overlap one another and cast a continuous shadow except in capillary loops so small that cells can pass singly. Retinal arcs are usually blue and seem to extend from the light source to the projected image of the blind spot. Halos may be produced by corneal epithelium, lens epithelium, or by lens fibers, acting as a diffraction grating.

I. E. Gaynon.

Matteucci, P. **Color perimetry.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, March-Apr., pp. 107-124.

The relative value of perimetry with white and colored test objects is thoroughly reviewed. The author concludes that color perimetry is more sensitive than white and that for every defect of the field found with the former there is a defect for white. It is difficult to determine accurately the peripheral limits of the field for color and there appears to be considerable difference in normal subjects, probably because of uncertainty between the chromatic sense and the sense of luminosity. Also the size of the target and the refractive error introduce further problems, as well as the question of attention and the intelligence of the subject.

Eugene M. Blake.

Moron Salas, José. **Procedure for supplying color perception to the color**

blind. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, May, pp. 363-367.

The author points out that there is no corrective treatment for color blindness. It is possible, however, by training, to enable the color blind individual to distinguish to some extent colors in ordinary or known surroundings. It has also been found that the red-green color-blind person is able to distinguish colors by the use of a red glass over one eye and a green glass over the other eye. While the latter may not be practical for general wear, the use of red-green glasses can be useful in situations wherein detailed color perception is needed. The use of these glasses is a valuable aid in the process of education of the red-green color-blind individual.

J. Wesley McKinney.

Reider, N. Phenomena of sensory suppression. Arch. Neurol. and Psychiat., 1946, v. 55, June, pp. 583-590.

Clinical studies on suppression phenomenon are reported in which stimuli originating in a normal, or relatively normal, sensory field tended to inhibit or abolish the perception of stimuli arising from an "affected" field.

When this phenomenon involves vision, in the presence of normal visual acuity and normal perimetric fields, it may be mistaken for a post-traumatic neurotic reaction. The mechanisms underlying the patho-physiologic changes are discussed. Emphasis is placed on the fact that the phenomenon may be elicited not only by contralateral but by homolateral stimuli. Theoretic implications of the phenomenon are mentioned.

Theodore M. Shapira.

Roveda, J. M. Jackson's cross cylinders. Arch. de Oft. de Buenos Aires, 1943, v. 18, Oct., p. 519.

After reviewing the history and giving

the description and technique of the cross cylinder, the author concludes that this procedure is the best method for the exact determination of astigmatism. The test for power and axis are very simple. The fact that the description of the use of the cross cylinder appears more complicated than it is in reality, is perhaps one of the reasons why it has not come into more general use. The principal reasons for its efficiency are (1) its minimal influence on the accommodation, (2) the presentation to the eye under study of a simultaneous increase and decrease of the elements of the tentative correction, and (3) its rapidity. A proper setting of the cross cylinder is essential for its successful use. (Illustrations, and bibliography.)

Plinio Montalván.

Sachs, E. Abnormal delay of visual perception. Arch. Neurol. and Psychiat., 1946, v. 56, Aug., pp. 198-206.

The Pulfrich effect, a remarkable stereoscopic and sensitive phenomenon, occurs when a smoked glass or polaroid glass is placed before one eye of a person who is observing a swinging pendulum. Suddenly the pendulum appears to describe a horizontal circle, to approach the observer and recede behind the initial vertical plane. The same effect may occur if with identical illumination the transmission of impulses between retina and visual cortex is delayed. A quantitative test was done on 74 male patients. Of these, five patients demonstrated an abnormal effect, two had the effect in one eye, and 35 matched the normal Pulfrich threshold.

Soto Eciolaza, J., and Olivella Casals, A. Contact glasses. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, May, pp. 352-362.

The indications and contraindications for the use of the Zeiss contact glasses together with the procedures for fitting them are discussed.

J. Wesley McKinney.

Thomson, L. C. Foveal color sensitivity. *Nature*, 1946, v. 157, June 15, p. 805.

Thomson and Wright have shown that there is an increase of sensitivity to blue light as the image of the matching field is moved from the center towards the edge of the central fovea, and the explanation of the colour difference here described may be that the fixation point was such that the two halves of the field lay upon areas of the retina of slightly different spectral sensitivity. The irregular shape of the curve may be due to the fact that the image of the matching field has a retinal position which depends upon the wave length. Some difference in the anatomical position of the fixation point for red, green, and blue light has been reported by Hartridge, and it may be that the position of the fixation point is a continuous function of the wave length when small matching fields are used.

Theodore M. Shapira.

de Vries, H. Mechanism of color discrimination and a new type of color blindness. *Nature*, 1946, v. 157, June 15, pp. 804-805.

In a previous letter, it was suggested that difference in the luminosity curves are caused by varying numbers of receptors. In order to find new evidence for this, it seemed worth while to study the intensity discrimination and the visual acuity of the three sets of receptors, as these functions depend upon the number of elements.

The author concludes that a flicker photometer may be a valuable instru-

ment in the detection of color blindness (but combined with the anomaloscope), especially because the color blind can adjust the minimum of flicker very accurately. Settings which suggest unusual sensitiveness or insensitiveness to red, point to a color discrimination.

Theodore M. Shapira.

Weiman, Maximiliano. Considerations regarding contact lenses. *Anales de la Soc. Méx. de Oft.*, etc., 1945, v. 20, July-Sept., pp. 107-114.

At the end of this short article the author remarks that premature commercial propaganda, by means of moving pictures and ignorant traveling agents, has given rise to deep disappointment in many purchasers of contact lenses.

W. H. Crisp.

Woelfflin, E. Is it possible to influence the congenital disturbances of the color sense? *Ophthalmologica*, 1945, v. 109, June, pp. 324-326.

Investigations by Studnitz showed certain oily globules in the retina of baby chicks. These globules were found in the outer parts of the cones and contained three pigments of the carotinoid group. Whether it is possible to influence color blindness by the use of these carotinoids can be determined by experiment only when they become available, in sufficient quantities to be fed to subjects over a long period of time.

OCULAR MOVEMENTS

Berens, C., and Romaine, H. H. A comparative study of sutures employed in surgery of the extraocular muscles. *Amer. Jour. Ophth.*, 1946, v. 29, Sept., pp. 1126-1134. (3 tables, 4 figures, references.)

Hartman, E. **Diagnosis and treatment of heterophorias.** *Ann. d'Ocul.*, 1946, v. 179, Feb., pp. 71-82.

After a prolonged stay in the United States, principally in New York, the author describes and evaluates the usual methods of examination and treatment of the phorias.

The tropias and phorias are defined and differentiated. Tests including the Maddox rod, cover and parallel tests for distance and near, are explained in detail. He suggests that convergence and divergence should be measured at 5 meters, and 30 centimeters. The importance of hygienic treatment is emphasized. The correction of hyperphoria is advised, and simple convergence and divergence exercises are explained.

The American methods are commented upon very favorably by the author and are here presented to French ophthalmologists. Charles A. Bahn.

Heim, M. **Nystagmus retractorius in encephalitis of Bang.** *Ophthalmologica.* 1945, v. 110, July-Aug., pp. 15-28.

Only fifteen cases of nystagmus retractorius have been published so far. There is a quick movement of the eyeball backward into the orbit followed by a slow passive return to its original position. The condition is always accompanied by a palsy of the elevators of the eyes that is usually supranuclear. The pathologic basis for the condition is damage by pressure or inflammation in the upper part of the posterior longitudinal bundle near the entrance of the aqueduct of Sylvius. The author observed a case of undulant fever of the Bang type, in which acute cerebral disturbances were found eight months after the infection. They included the above described symptoms and some

associated nuclear disturbances of the eye muscles. Encephalitis in the tegmentum near the entrance to the aqueduct of Sylvius was assumed to be the cause in this patient, but recovery occurred in two weeks without adding new facts to the picture of nystagmus retractorius. All the cases described in the literature are summarized in the article. (Bibliography.)

Max Hirschfelder.

Hermann, K., and Hall, I. S. **Sphenoidal mucocele as a cause of the ophthalmoplegic migraine syndrome.** *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, pp. 154-164.

The clinical diagnosis of the "ophthalmoplegic migraine syndrome" has been used when there is severe unilateral supraorbital pain followed by partial or complete homolateral oculomotor paralysis. The paralysis develops quickly and recedes gradually. With recurrent attacks regression of the ocular palsy becomes less complete until eventually a more or less complete palsy remains. Bramwell suggested that the origin of this syndrome is vascular. A leaking aneurysm, or an artery or an unruptured aneurysm may make transient pressure on the affected nerve. The authors have demonstrated by means of arteriograms that congenital basal cerebral aneurysm is the commonest cause of the ophthalmoplegic migraine syndrome.

They add a case report. A man had recurrent headaches since 1924. The headaches gradually became more frequent and with each one facial pain became more severe. Six months ago the left upper eyelid became involved and the vision became blurred. A mucocele of the sphenoid sinus was found and after an operation in which the anterior

wall of the cyst was removed recovery was rapid. (7 illustrations.)

CONJUNCTIVA

Freitas, Orlando de. **Bacterioscopic examinations of conjunctival secretions.** *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 179-195.

The results obtained from 3,445 bacterioscopic examinations of conjunctival secretions are analyzed. About one half the examinations were in cases of conjunctivitis and about one half preoperative. In the cases of conjunctivitis the predominant organism was the Koch-Weeks bacillus, with 16.8 percent, followed by the pneumococcus with 16.1 percent. In the preoperative cases, almost one half were negative, and the positive cases showed a predominance of diphtheroid bacilli and staphylococci. (4 graphs, references.)

W. H. Crisp.

Jackson, W. P. U. **The syndrome known as "Reiter's disease."** *Brit. Med. Jour.*, 1946, No. 4466, Aug. 10, pp. 197-199.

The triad of polyarthritis of the large joints, nonspecific urethritis, and bilateral catarrhal or purulent conjunctivitis is nonvenereal and of undetermined etiology. Episcleritis and keratoderma blennorrhagia may also be part of the picture. Response to sulfadiazine therapy is good. Three cases are reported.

I. E. Gaynon.

Jona, Sergio. **Reticulo-histiocytoma of the conjunctiva.** *Rassegna Ital. d'Ottal.*, 1946, v. 15, March-Apr., pp. 81-93.

Tumors of the reticulo-endothelial system are rare and only two previous

cases of this neoplasm have been reported as occurring in the conjunctiva. Certain conditions are necessary to make the diagnosis: cells which are morphologically mesenchymal, intimate relation to the supporting fibers, phagocytic properties, and evolution towards a pluricellular type.

Jona's patient was a man, 64 years of age whose left eye showed a thick tumor of the bulbar conjunctiva of the left eye of two years duration. He concludes that such tumors result from a proliferation of the peri-adventitia of the blood vessels. Eugene M. Blake.

Mihalyhegyi, G. **A new contribution to the origin of the abscess in the bulbar conjunctiva.** *Ophthalmologica*, 1945, v. 109, Apr.-May, pp. 265-268.

Abscesses in the bulbar conjunctiva are rare. They usually occur around foreign bodies or in cases of septicemia. The author observed a patient who developed an abscess of the bulbar conjunctiva after a hordeolum, obviously through contact with the infected tissue.

CORNEA AND SCLERA

Alberstadt, N. F. and Price, A. H. **Corneal ulcer treated with streptomycin.** *Amer. Jour. Ophth.*, 1946, v. 29, Sept., pp. 1106-1111. (References, 1 table.)

Allenic. **Local sulfonamide therapy in hypopyon ulcers.** *Ann. d'Ocul.*, 1945, v. 178, Dec., pp. 561-566.

The author has employed sulfonamide powder satisfactorily in infectious ulcers since 1942. He uses local anesthesia but avoids the excessive use of cocaine. Two sulfonamide applications are used daily. In three years no enucleations have been found necessary in corneal ulcers, except in eyes that were lost when first seen.

In hypopyon ulcers with lacrimal impermeability and infection, in herpes, spring catarrh, and in rodent ulcers, this treatment was used as an adjunct to other therapy.

More rapid cicatrization with less degeneration apparently followed powdered sulfonamide therapy. The most favorable reactions were observed in infected phlyctenular ulcers. Subconjunctival injection of sulfamids is not advised because of frequent hemorrhage. Five illustrated cases are described.

Blaine, G., Dollar, J. M., Sorsby, A. The use of plastic materials for scleral wounds. *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, p. 187.

The authors report on the use of plastic materials in the treatment of scleral wounds. Fibrinogen plastic, calcium alginate, and methyl methacrylate were used.

They concluded that an inert nonab-

sorbable substance does not influence wound healing in the sclera. Absorbable plastic materials such as fibrinogen and, to a lesser extent calcium alginate exercise a favorable influence.

Beulah Cushman.

Bruechner, R. A case of Sjögren's syndrome, successfully treated with Perandren. *Ophthalmologica*, 1945, v. 110, July-Aug., pp. 37-42.

Sjögren's syndrome, keratoconjunctivitis sicca, is associated with dryness in the naso-pharynx, achylia, and chronic arthritis. Elderly women are predisposed and it is not certain whether the condition is an avitaminosis or a disturbance of the organs of internal secretion. In a woman 47 years of age, the disease responded remarkably well to oral doses of male hormone (methyltestosterone, Perandren). Her symptoms immediately returned when this substitution therapy was interrupted and the patient improved with the return to the treatment. This observation makes a disturbance of the internal secretion seem probable. (Literature.)

Jona, S. A study of the chemical nature of the Kayser-Fleischer ring by ultra-violet light. *Rassegna Ital. d'Ottal.*, 1946, v. 15, May-June, pp. 191-200.

Various theories as to the origin of the pigment in the Kayser-Fleischer ring are reviewed. Fleischer first stated that the source was not iron but probably biliary pigment. Later he concluded that it came from degenerated hemoglobin. Rumpel and Söldner stated that the color of the ring was due to silver, and Kubik found spectroscopically that it was urobilin. Copper was also considered to be the source of the color. Jona studied a case by filtered ultra-violet light and concludes that the pigment is neither copper nor urobilin but probably a complex organic substance not definitely determined.

Eugene M. Blake.

Klar, R. Corneal involvement in vernal conjunctivitis. *Klin. M. f. Augenh.*, 1943, v. 109, May-June, p. 385.

In a man, 22 years of age, who had suffered from the palpebral type of vernal conjunctivitis for seven years, small proliferations occurred at the limbus during one recurrence. At the same time punctate and comma-shaped subepithelial and epithelial grayish-white opacities that could be stained with fluorescein appeared in the center of the cornea. Treatment consisted of dry hot applications and 3-percent boric acid ointment. The foci gradually coalesced and other punctate and elongated opacities developed near the periphery. In the vicinity of the circumscribed limbal proliferation no corneal lesions were seen. The process healed completely without leaving permanent opacities. (References.)

Malling H. Congenital parenchymatous (non-luetic) keratitis. *Acta Ophth.*, 1944, v. 22, pt. 2, pp. 141-146.

Two cases are reported and a similar observation reported by Tertsch is briefly referred to. An infant was seen when one month old, with a bilateral corneal affection resembling parenchy-

matous keratitis. The lesion was characterized by scattered, fairly massive, diffuse grayish spots in the corneal parenchyma, and deep vessels extending 1 to 3 mm. into the cornea. The left cornea was macerated with large epithelial erosions, especially in the center. Several months later the lesion had healed. The right cornea was left with a few scattered nebulae and the left with dense central maculae. The other patient, a woman 40 years of age, had massive, smooth, irregularly circumscribed maculae in the lower portion of each cornea, distortion of the pupils, and left anterior polar cataract in the left eye. The pathogenesis of the affection is discussed, and it is believed that it is an extrauterine inflammatory affection. (Illustration.) Ray K. Daily.

Panzardi, D. The Stähli's corneal line in trachomatous patients. *Boll. d'Ocul.*, 1944, v. 23, July-Sept., pp. 195-205.

With the slit lamp the writer systematically studied the condition of the cornea of 100 patients with old trachoma. In all of them there was super-

ficial linear horizontal pigmentation in the lower half of the cornea that resembled the senile line of Stähli. The line had a decided horizontal course and was curvilinear or broken. The position of the line corresponds to the palpebral fissure through which an irritating substance or evaporation could cause further damage to the already badly affected cornea. (Bibliography.)

Melchior Lombardo.

v. Papolczy, F. Pathogenesis and therapy of serpiginous corneal ulcer. *Klin. M. f. Augenh.*, 1943, v. 109, May-June, p. 361.

Serpiginous corneal ulcer can occur at any age and in both sexes. The incidence is higher in males (65 percent) and after 40 years of age. Coexistent dacryocystitis was observed in 25 percent of patients. In 25.34 percent of the patients pneumococci were found, in 36.9 percent staphylococcus albus, and less commonly staphylococcus aureus, diplobacillus, streptococcus, and xerosis bacillus. Even the last species can produce the disease. It is recommended that cultures be taken not only from the secretion of the conjunctival sac but also from the ulcer itself. Local treatment with wetol, a preparation of vitamins A and D and iodine in linseed oil or cod-liver oil, proved most beneficial. The author used a mixture of equal parts of wetol and cod-liver oil, which is not only a strong antiseptic but also a stimulant of tissue growth. In addition he advocates such surgical procedures as cautious removal of the overhanging edge of the ulcer, cauterization, removal of exudate from the anterior chamber, trephining, and paracentesis. Pavisc, Z. Treatment of serpiginous ulcer with the sulfapyrimidine prepara-

tion "Debenal." *Ophthalmologica*, 1945, v. 109, Apr.-May, pp. 227-235.

Fourteen cases of seriginous ulcer of the cornea which were treated orally with sulfapyrimidine are reported. The results were satisfactory in ulcers that were not too far advanced. The drug was well tolerated by the patients, all of whom were over 47 years of age. Only in far advanced ulcers were other measures such as steam cautery and conjunctival covering necessary. The literature on the subject of local and general sulfonamide therapy of seriginous ulcers is briefly reviewed. (Bibliography.) Max Hirschfelder.

Pirie, A. Ascorbic acid content of cornea. *Biochem. J.*, 1946, v. 40, no. 1, pp. 96-100.

The ascorbic acid content of corneas of cattle and rabbits was determined when excised immediately after death, and after chemical damage had had time to occur. The concentration in the epithelium was found to be much higher than in the stroma. About one half the total amount of ascorbic acid in the cornea was found in the epithelium. The amount in the stroma was about equal to that in the aqueous. It was deduced that the endothelium is permeable to ascorbic acid. After injury with $\beta\beta'$ -dichlorodiethyl sulphide the concentration of ascorbic acid in the cornea was decreased. (5 tables, references.) Bennett W. Muir.

Richards, J. M. and Romaine, H. H. Keratoconjunctivitis sicca. *Amer. Jour. Ophth.*, 1946, v. 29, Sept., pp. 1121-1125. (See section 17, Systemic diseases and parasites.)

Riise, Per. Transplantation of the entire cornea. *Acta Ophth.* 1943, v. 21, pt. 1-2, pp. 26-30.

In two eyes in which the cornea had been lost through a seriginous ulceration so severe that iris and lens were exposed, an entire cornea was implanted. In one case the implant was taken from a cadaver, and in the other from an eye enucleated because of a choroidal tumor. Both implants took. Five months after the transplantation one cornea was opaque peripherally, but clear enough in the center to permit visibility of the pupil. Vision was hand movements in front of the eye. The second case was in its ninth post-operative day when this report was made. (2 photographs.)

Sezer, D. N. Hereditary corneal dystrophy. *Oto-Nöro-Oft.*, 1946, v. 1, pp. 6-15.

The author reports the first three cases of corneal dystrophy in Turkish literature. In a man, 45 years of age, white subepithelial plaques coalesced to form a discoid opacity in the central area of each cornea. In a man 24 years of age, who had complained of poor vision for five years, biomicroscopic examination revealed many small brown and gray opacities of varying size in the superficial layers of the parenchyma in the pupillary area of each cornea. The epithelium was irregular and nodular. In the third case a man 21 years of age complained of decreased vision, pain and photophobia. The entire cornea seemed veiled owing largely to the

increased reflection in the region of Bowman's membrane. I. E. Gaynon.

Smith, Arthur. Survey of the treatment of traumatic corneal ulcer. 1941-1944, Royal Hospital, Sheffield. Brit. Jour. Ophth., 1946, v. 30, March, pp. 178-186.

By means of graphs 262 cases of corneal ulcers are analyzed. Annual incidence, age, length of stay in hospital, visual acuity, and vision as related to age are considered. Treatment consisted of intravenous protein therapy combined with internal sulfonamide administration. Cauterization was purposely omitted and results were uniformly good. Morris Kaplan.

Summers, T. C. Penicillin and vitamin C in the treatment of hypopyon ulcer. Brit. Jour. Ophth., 1946, v. 30, March, pp. 129-134.

Twelve cases of hypopyon ulcer are reported. Treatment consisted of immediate cauterization, instillation of penicillin (200 units per c.c. every hour during the day and every three hours during the night) and atropine, the constant use of a hot pad, short wave diathermy, and an injection of 500 mg. of vitamin C. Results were much superior than with regimens previously used. The author believes that penicillin and vitamin C combined are considerably more effective than either alone. (13 colored illustrations.)

Morris Kaplan.

Svoboda, J. Further experiences with the implantation of buccal mucosa in eye diseases. Časopis Lekarů Ceskyh, 1946, v. 85, June 14, pp. 797-800.

Implantation of buccal mucosa according to Denig was carried out in 47 patients with trachomatous pannus. Of

22 who were examined one year after the operation, irritation was present in two and six had recurrence. Of 114 patients operated upon for pterygium, seven had insufficient cosmetic improvement and seven had recurrence. Sixteen patients were treated by this method for burns with satisfactory outcome in all but two. O. Felsenfeld.

Thomas, C. I. Corneal transplantation and preliminary iridectomy. Arch. of Ophth., 1946, v. 35, Feb., pp. 170-172.

Iridectomy is recommended as a preliminary to the corneal transplantation operation for the following reasons: it enables the surgeon to estimate the amount of postoperative reaction that may follow; it allows for more rapid refilling of the anterior chamber; a prolapse of the iris into the wound after the transplantation is less likely. Iridectomy may prove dangerous and should be approached with caution in an eye which has the relatively unfavorable, deeply scarred, somewhat vascular cornea and in which, when the anterior chamber is opened, the iris is found to be smooth and bound down tightly to the lens. Loss of vitreous frequently follows an attempt to do an iridectomy in such an eye.

John C. Long.

Valerio, M. Keratitis sicca and keratitis filamentosa. Rassegna Ital. d'Ottol., 1946, v. 15, March-Apr., pp. 144-151.

Keratoconjunctivitis sicca is simply the expression of the corneal and conjunctival alterations which are the natural consequence of a destruction of the secretory tissues of the lacrimal gland, and independent of the factors which cause this destruction. The presence or absence of filaments upon the

cornea has no particular significance, except that it is one of the principal causes of the patient's discomfort. There is another form of filamentous keratitis, that is seen in herpes of the cornea.

Verdaguer, Juan (P). Therapy of superficial keratitis. Arch. Chilenos de Oft., 1945, 1st yr. May-June, July-August, nos. 6 and 7, p. 13.

The subject is discussed under the following heads; morphologic description of epithelial keratitis, etiology of superficial keratitis, infectious keratitis, degenerative keratitis, relapsing erosion of the cornea, other indications for subconjunctival autohemotherapy.

W. H. Crisp.

Werner, K. The treatment of serpiginous corneal ulcer with the sulfonamid preparation Cibazol. Klin. M. f. Augenh., 1943, v. 109, May-June, p. 376.

Of 30 serpiginous ulcers that varied in size from 1.5 to 6 mm., 27 were treated successfully with cibazol given internally. Locally only scopolamine was instilled. The patients were kept in bed and the diseased eye was bandaged with a metal shield. Fifty percent of the eyes were infected by pneumococci, the remainder by staphylococcus pyogenes aureus and citreus, xerosis bacillus, streptococcus viridans, and colon bacillus, either alone or as part of a mixed infection. The average stay in the hospital was eight to nine days. Two patients were treated ambulantly. Two of the three eyes that did not respond to the treatment became blind from spontaneous perforation, and in one resistant recurrences made electrocauterization necessary. No surgical methods except extirpation of infected tear sacs were used. Resulting vision in nine patients was 1.0, in 11 it was

between 0.5 and 0.9, and in five it was less than 0.5. (References.)

Woods, A. C. Nummular keratitis and ocular brucellosis. Arch. of Ophth., 1946, v. 35, May, pp. 490-508.

In a previous paper published in collaboration with Guyton, it was suggested that in some instances the nummular keratitis of Dimmer, might be due to an infection with Brucella. Several further observations have been made which strengthen this opinion. The clinical and experimental observations which prompt this belief are presented.

A complete discussion of the history of the terminology is given.

The confused literature on nummular keratitis suggests that more than one clinical entity may have been described under this term. Five isolated, sporadic cases are reported. In all of the patients the classic picture of nummular infiltrates in the cornea and, likewise, serologic or allergic evidences of brucellosis were present. A typical nummular keratitis can be produced in experimental animals by proper inoculation of the eyes with Brucella organisms. It seems probable that some of the nummular keratitis reported may actually have been corneal brucellosis. The term Brucella nummular keratitis is suggested.

R. W. Danielson.

Effect of antiseptics on regeneration of corneal epithelium. Bull. U. S. Army Med. Dept., 1946, p. 257.

The corneal epithelium was rubbed off by gauze in the previously cocaine-ized eyes of a number of adult rabbits. The right eyes of the rabbits were treated with normal saline solution in a quantity similar to the drug solutions used in the left eyes. The solutions used

in the left eyes were: aqueous solutions of mild silver protein, 10-percent; zinc sulfate, 0.5-percent; mercurochrome, 2-percent; phemerol, 1:2,500 in 2-percent boric acid solution; mercuric oxycyanide 1-5,000; metaphen 1-2,500; merthiolate 1-2,500; acriflavine 1-1,000; zephrian chloride 1-3,000; penicillin 2,500 oxford units per c.c.; and sodium sulfathiazole, 2-percent.

During the first 24 hours the right and left eyes of each rabbit had equally hazy corneas and equal conjunctival congestion. Within four to six days the right eyes were clinically normal, whereas the left eyes had large denuded areas.

The investigators concluded that the local antiseptics ordinarily used in ocular therapeutics considerably delayed the healing process in the corneal epithelium of rabbits. In most instances the use of these drugs resulted in a permanent opacity of the cornea. The histologic changes in all the corneas that were examined were alike, which suggests that all the chemicals produced the same nonspecific irritation. Sodium sulfathiazole and penicillin neither delayed regeneration nor produced opacities.

The authors feel that the use of common local antiseptics should be limited to those injuries in which there is a probability of infection. F. M. Crage.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Atkinson, Donald. The artificial pupil in the restoration of vision. *J. Internat. Coll. Surgeons*, 1946, v. 9, May-June, pp. 365-369.

The author presents four cases and discusses his simplified method of creat-

ing an artificial central opening in the iris in aphakic eyes in which the pupil has been sealed by exudates. This consists of a corneal section in which the knife, cutting edge downward, is made to penetrate the cornea 4 mm. from the limbus, after which it is forced through the iris and passed forward 6 mm. where it again enters the anterior chamber. The counter puncture in the cornea is made and the section is not finished, as the elasticity of the iris will cause a coloboma to occur. The knife is then withdrawn. (Four figures.)

I. E. Gaynon.

Emmelin, N., and Palm, E. On the presence of histamine in aqueous humor. *Acta Ophth.*, 1944, v. 22, pt. 2, pp. 117-130.

The material for this laboratory investigation consists of the aqueous of the cat, dog, rabbit, and ox. The intestine of the guinea pig was used as the test material, for histamine produces muscular contraction. The data, reported graphically, show that a biologically active substance is present in the aqueous of these animals, which causes histamine-like contraction of the guinea-pig intestine and a bronchial constriction. The substance producing these reactions is destroyed by boiling in alkaline, but not in acid solution. The effect on the guinea pig intestine is counteracted by thymoxietyldiethylamine but not by atropine. The intravenous injection of histamine raises the blood histamine content but does not increase the histamine content of the aqueous.

Esteban, Mario. A rare postoperative complication: iridocyclitis from penetration of a greasy substance into the eye. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, May, pp. 378-384.

A postoperative iridocyclitis beginning on the eighth day after an uncomplicated intracapsular cataract extraction is reported. The eye was very painful for more than two months. A small globule of grease was noted on the hyaloid membrane with the slit lamp. It was thought to be a particle of ointment that had been introduced into the eye at the time of operation. Chemical irritants given off by the grease caused the iridocyclitis. The particle was not absorbed but eventually seemed to be at least partially encapsulated by fibrin from the iris. J. Wesley McKinney.

Franceschetti, A., Valerio, M., and Babel, J. Recurrent aphthous uveitis with mucocutaneous lesions. *Arch. of Ophth.*, 1946, v. 35, May, pp. 469-489.

During the last few years a new syndrome has been described in the European literature of dermatology and ophthalmology, a syndrome characterized by periodically recurring uveitis and a group of mucous and cutaneous symptoms.

The clinical evolution of this disease is characteristic. It affects young people, generally between the ages of 20 and 30 years, and evolves slowly over a period of years. The illness is essentially characterized by its recurrence, and especially by the periodicity of the attacks.

The beginning of the illness is insidious and is characterized by the sudden appearance of banal buccal aphthae. Uveitis is in general the characteristic and dominant feature of the syndrome. No specific or valuable treatment has been found.

The authors report five cases in detail and discuss the various theories of etiology. Of the various hypotheses, that of a virus infection seems the most probable, although it is necessary to

introduce another factor, which is the sensitization of the organism. This allergy, however, seems to be secondary, and not the initial cause of the disease as in the analogous ocular disorders of the rheumatic type.

The extremely frequent coexistence of gastrointestinal disturbances should be remembered. (57 references and 4 figures.) R. W. Danielson.

Godtfredsen, Erik. The frequency of secondary carcinomas in the choroid. *Acta Ophth.*, 1944, v. 22, pt. 4, pp. 394-400.

Six cases of metastatic choroidal tumor were found among 8,000 patients with cancer at the Radium Center. They constituted between one-third and one-half of the total number of intraocular tumors. Contrary to published data this investigation shows that metastasis in the choroid from pulmonary and mammary cancer is equally frequent. Ray K. Daily.

Godtfredsen, Erik. Choroid metastases in chorionepithelioma of the testicle. *Acta Ophth.*, 1944, v. 22, pt. 3, pp. 300-310.

The literature contains five cases of ocular metastasis of a chorionepithelioma; three in women, and two in men. The author's patient a man, 18 years of age, died one year after the appearance of this tumor in the testicle and 20 days after the appearance of the ocular metastasis. Autopsy revealed metastases in the internal organs and cerebrum. (Microphotograph.)

Guglianetti, L. A new symptom of sympathetic ophthalmia. *Rassegna Ital. d'Ottal.*, 1946, v. 15, nos. 1 and 2, p. 5.

Since sympathetic ophthalmia manifests itself predominantly in the an-

terior segment or the posterior segment of the eye, Guglianetti inquired whether there might be early changes in the field of vision which would be diagnostic. Using the Maggiore perimeter and reduced illumination he found an annular scotoma between the macula and the periphery both for white and colored test objects in two patients. A third patient revealed a ring scotoma about the macula very early in the course of the disease. Further studies are necessary to determine the value of this test. Eugene M. Blake.

Haar, M. **Reiter's disease.** *Acta Ophth.*, 1945, v. 23, pt. 2, pp. 143-150. (See Section 5, Conjunctiva.)

Hebert, Emile. **An exceptional complication of furunculosis.** *Ann. d'Ocul.*, 1945, v. 178, Dec., pp. 556-560.

A man, 25 years of age, with anthrax, developed a furuncle in the left nose with ocular redness, and iritis in left eye. One week later the anterior ocular inflammatory symptoms subsided. A white spot as large as the optic disc and a small hemorrhage were observed near the macula. Choroidal detachment in one of the upper quadrants in each eye followed probably as a result of a choroidal lesion. One month later the detachment had completely disappeared in the right eye, but not in the left eye. Sulfonamides were not well tolerated. Two months later only photophobia and small spots in the retina with slight striation persisted. The sudden onset, normal tension, and normal transillumination made choroidal tumor seem unlikely.

Pathologically the condition was a staphylococcus septicemia involving the orbit and uveal tract with a bilateral choroidal detachment. The detachment

was attributed to suprachoroidal inflammation. Choroidal detachment is not infrequent after intraocular operations and usually becomes reattached without serious complications.

Charles A. Bahn.

Herrmann, Heinz. **Enzymatic oxidations in ciliary processes.** *Bull. Johns Hopkins Hosp.*, 1946, v. 78, March, pp. 119-125.

Separated fractions of the cell debris of the epithelium of the ciliary processes were studied for their chemical composition and their enzymatic activities. Marked differences were found in both these factors. Different types of granules contain enzyme aggregates of different composition which could vary the local variation of cellular metabolism. Francis M. Crage.

Krause, A. C. and Smith, L. F. **The therapeutic treatment of uveitis associated with toxoplasmosis.** *Amer. Jour. Ophth.*, 1946, v. 29, August, pp. 977-980. (References.)

Larsson, S., and Osterlind, G. **Studies into the causes of senile miosis and rigidity of the pupil.** *Acta Ophth.*, 1943, v. 21, pt. 1-2, pp. 1-25.

The authors review the literature and report 14 cases which they investigated. The 14 patients, 69 to 85 years of age, were subjected to a detailed preoperative biomicroscopic examination of the rigidity and structure of the iris. Most of the eyes had a more or less pronounced depigmentation of the free iris border, and in a number of cases the depigmented border was transformed into a structureless grayish-white homogeneous membrane. These changes in the iris had no definite relation to the degree of pupillary mobility, and were

not proportionate to the extent of histologically verifiable hyaline degeneration in the iris.

Segments of iris were excised and examined histologically.

The histological changes were principally sclerosis of the iris vessels, and more or less extensive hyaline degeneration near the free pupillary border and in the connective tissue layer between the sphincter and the pigment epithelium. The extent of these changes appeared to be in close relation to the degree of pupillary mobility. Atrophy and degenerative processes in the sphincter and dilator of the pupil were found in a number of the iris segments, and it seems certain that extreme rigidity of the pupil is always associated with these changes in the iris musculature. The anatomical background of senile miosis is thus shown to be primarily arteriosclerosis of the vessels of the iris, hyaline changes of the stroma, and degeneration of the musculature. Each one of these changes will make normal dilatation more difficult, but not impossible. All the changes combined and in advanced stages result in complete immobility of the pupil.

Lund, Axel. Chronic iridocyclitis. *Acta Ophth.*, 1944, v. 22, pt. 2, pp. 176-192.

The case histories of 88 patients treated at the Finsen Institute were analyzed for data on the effectiveness of the treatment, etiology, and prognosis. The average period of observation was five years. The treatment consisted principally of carbon arc light baths and injections of tebeoprotein. Thirty patients were men and 58 women. The morbidity is greatest between the ages of 20 and 30 years, and

in women there is a rise in the morbidity near the age of 50 years. The average duration of the disease was 14½ months; it had a marked relation to the age of the patient at the onset of the disease; 39 months for patients under 20 years of age, and 7 months for people over 50. Of 151 eyes 136 became quiescent, although there were relapses in 56 eyes. As a rule the relapses were mild. Nearly one half of the eyes recovered with normal vision. Sixty-three percent had good reading vision, and 23 percent had orientating vision. The poor visual results were due to complications, such as secondary glaucoma, central lesions, optic neuritis, retinal detachment, and cataract. In all patients except those who had cataract the poor visual results were irreparable. Nine patients with a cataract were operated upon; in five the result was good reading vision. In one there was a recurrence of the inflammatory process. One half of the patients had roentgenographic evidence of lesions in the lungs.

Marback, H. Spontaneous cyst of the iris. *Arquivos Brasileiros de Oft.*, 1946, v. 9, Feb., pp. 1-9.

A woman, aged 27 years, came complaining of a small spot on the right iris, said to have been noticed only for the past 12 years. The eye was normal in every other respect and the visual acuity was 1.0. The iris moved freely. The pupil was slightly oblong. In the anterior chamber, in the region of the chamber angle between the 9:30 and the 10:30 o'clock positions, was seen a small cyst, hemispherical in form, and whose radius was from 1.5 to 2 mm. in length. Dilatation of the pupil demonstrated the absence of synechia. Under the biomicroscope, the walls of

the cyst were transparent and extremely thin. There were two small pigmented areas in the posterior wall, and the anterior wall contained meshes of iris stroma and was traversed by capillaries. The patient was urged to undergo excision of the cyst by means of an iridectomy, but refused such action on account of the absence of inconvenience from the cysts. After $2\frac{1}{2}$ years no appreciable change was discovered in size or appearance of the cyst. (References.) W. H. Crisp.

Matthews, G. W. and Hollabaugh. Uveitis with secondary glaucoma. Bull. U. S. Army Med. Dept., March, 1946, p. 364.

A white male, aged 42 years, was hospitalized for a painful, moderately congested left eye. The vision was 20/200, tension (Schiotz) 40 mm., the vitreous was cloudy, and the cornea had a few deposits on its posterior surface. There was no visible choroidal lesion. The diagnosis was acute uveitis with secondary glaucoma.

Laboratory tests and clinical examinations were negative. X-ray films revealed a small lower fourth molar completely covered by bone. After removal of the tooth caseous exudate escaped. Adjacent to the tooth and posterior to it was a large rough cystic sac.

Two days after operation the eye was free from pain, and tension was 20. Two weeks later the vision was 20/30 and the eye was normal except for a few vitreous opacities. F. M. Crage.

Olsson, G. F. A common species of clinically observable spontaneous cysts in the anterior uveal tract. Acta Ophth., 1944, v. 22, pt. 4, pp. 319-340.

The literature is reviewed and 15 cases of spontaneous cysts situated on the posterior surface of the iris are re-

ported. Twelve of the patients were women, and no patient was older than fifty years. There were no symptoms of irritation. The cysts produced a slight elevation on the anterior surface of the iris, and they could be seen on the posterior surface only after maximal dilatation of the pupil. The pigmentation of the walls of the cysts varied in intensity from slight to very great. The origin of the cysts is discussed; the author believes that the faintly pigmented ones originate from a circumscribed separation of the limitans iridis, and the highly pigmented cysts are formed by the pigment epithelium. Usually no therapy is indicated. (2 photographs.) Ray K. Daily.

Pirie, A., and Simpson, D. Preparation of a fluorescent substance from the eye of the dogfish, *Squalus Acanthias*. Biochem. J., 1946, v. 40, no. 1, pp. 14-20.

A method is described for the preparation of a blue fluorescent material that is largely confined to the choroid, with perhaps traces in the iris. Chemical and spectroscopic evidence makes it probable that the substance is xanthopterin and not ichthyopterin. A similar substance was found in the eyes of Alligator Mississippiensis. The presence of guanine in the choroidal tapetum was confirmed. (1 figure, 1 table, references.) Bennett W. Muir.

Vidal, F. and Malbrán, J. Studies on the chemical composition of the aqueous humor of the cat. VII. pH. Arch. de Oft. de Buenos Aires, 1943, v. 18, Oct., p. 506.

The authors studied the pH of the aqueous humor of the cat. The determinations were calculated with v. Brehmer's hemo-ionometer using an electrode of quinidrone which allows

measurements of the pH between 6 and 8.5. The average figure in 19 eyes was 7.51 for aqueous of first formation and 7.52 for aqueous of second formation. The pH of the aqueous humor in cats is more alkaline than that of the blood in the same animal. Under abnormal conditions the authors obtained slightly higher figures, 7.55 and 7.57. (Tables, bibliography.) Plino Montalván.

Zeeman, W. P. C. The diagnosis of a flat sarcoma of the choroid and the histological substratum of the changes observed with the ophthalmoscope. *Acta Ophth.*, 1943, v. 21, pts. 1-2, pp. 47-60.

A clinical and histo-pathological report of a case, correlating the ophthalmoscopic picture with the microscopic changes. Reference is made to a case reported by Meller as a pseudosarcoma choroidea and the correctness of his diagnosis is questioned. To support his contention that Meller's case was a sarcoma the author describes and illustrates the microscpic findings in an enucleated globe similar to the one reported by Meller. In this case the extension of the tumor along a ciliary nerve left no doubt as to its identity. (8 illustrations.) Ray K. Daily.

GLAUCOMA AND OCULAR TENSION

Cristini, G. Alterations of general arterial pressure as a factor in the causation of glaucoma. *Rassegna Ital. d'Ottal.*, 1946, v. 15, March-Apr., pp. 125-143.

Cristini stresses the need to study the variations of the general circulation in the evaluation of the tension in glaucoma. He reviews the present knowledge of the circulatory and nervous physiology of the uvea and its relation-

ship to the regulation of the tension of the eye. Twenty patients with glaucoma were tested. The systolic blood pressure and the ocular tension after inhalation of amyl nitrite, after withdrawal of 500 c.c. of blood, and after compression of the eyeball were recorded. The author concludes that alterations in both the arterial and venous vessels of the uvea are fundamental causes of chronic glaucoma. This hypothesis is supported by the diverse response to hypotensive substances in glaucoma patients.

Eugene M. Blake.

Gallenga, Riccardo. Operative treatment of hydrophthalmos. *Rassenga Ital. d'Ottal.*, 1946, v. 15, May-June, pp. 161-164.

The writer finds that the removal of the lens is the best treatment for congenital glaucoma. After dilating the pupil with atropine he divides the capsule and lens fibers with a double-edged knife. Four to eight days later he extracts the swollen lens matter by aspiration, through a small opening at the limbus above. For anesthesia chloral hydrate and a retrobulbar injection of novocain without adrenaline are used.

Four patients were operated upon by the above technic with satisfactory results and all were under four years of age. Gallenga feels that the lens is an etiologic factor in buphthalmos, and its removal is indicated for the same reason that this treatment is helpful in congenital aniridia and in high myopia.

McDonald, Phillip Robb. Treatment of glaucoma with di-isopropyl fluorophosphate. *Amer. Jour. Ophth.*, 1946, v. 29, Sept., pp. 1071-1081. (9 figures, 1 table, references.)

Oezerengin, T. Two cases of congestive glaucoma with acute rheumatism. *Göz Kliniği*, 1945, v. 3, no. 3, pp. 35-39.

The author presents his observations on two women who developed congestive glaucoma during their convalescence from acute rheumatism. One woman is suffering from "confusion of the endocrines" and the other hypertension. He believes the glaucoma is caused by an allergic response to the infection. I. E. Gaynon.

Penido Burnier, Jr. Threshold of ocular tension. *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 168-177.

A man aged 52 years came complaining of failing vision. The corrected vision of the right eye was 0.3, that of the left eye 0.7. Ophthalmoscopy showed marked excavation of the optic discs, extending to the disc margins and accompanied by pallor which was more evident in the right eye. The tension of the right eye with the Schiötz instrument was 17 mm., the tension with the McLean instrument 32 mm. The fields were somewhat contracted, and the right eye had a typical Bjerrum scotoma. Reduction of tension with miotics, to something like 3 or 4 mm. (Schiötz), caused some improvement in vision. (7 illustrations, including 4 pairs of visual fields.) W. H. Crisp.

Penido Burnier and Souza Queiroz. Familial glaucoma secondary to spontaneous, homochronous, and hereditary dislocation of the crystalline lens. *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 57-75.

The authors give the histories of four patients, three brothers aged 45,

65, and 50 years respectively, and a cousin of the three aged 52 years. All four developed subluxation of the crystalline lenses, followed by acute glaucoma. Iridectomy did not relieve the glaucoma, but the ocular tension became normal after extraction of the dislocated lens. On the whole the visual results were good after operation, although one patient was less fortunate in this respect because he at first refused extraction of the lens. The authors describe and illustrate the genealogic tree of the affected family, showing 11 positive out of 18 individuals in three generations. The authors agree with Vogt, who presented a similar family record, in attributing the spontaneous dislocation to presenile degeneration of the zonula, hereditary in character. Intracapsular extraction is regarded as the treatment of choice. (Bibliography.)

W. H. Crisp.

Regoli, Attilio. The consensual ophthalmotonic reaction. *Boll. d'Ocul.*, 1944, v. 23, July-Sept., pp. 129-165.

A summary of the subject as it appears in the literature precedes the article. The author reports in tabulated form the results obtained in patients and rabbits. In his own experience the reaction manifests itself after such procedures as paracentesis of the anterior chamber, galvano-cauterization of the sclera, antiglaucomatous procedures, enucleation of the globe, and surgical procedures on the lacrimal passages. The reaction is probably a reflex phenomenon based on vascular changes which, through centers and associated fibers of a vasomotor system is transmitted consensually to the other eye. (Bibliography.)

Melchior Lombardo.

Riise, Per. Experiences with Holth's iridencleisis. *Acta Ophth.*, 1943, v. 21, pts. 1-2, pp. 31-46.

This is a detailed analysis of 199 iridencleisis operations performed on glaucoma patients. Normalization of tension, relation of tension to visible filtration, immediate and late postoperative complications, conservation of central and peripheral visual acuity, and postoperative refractive changes are considered. The material comprises acute, secondary, and chronic simple glaucoma, and its value lies in the fact that all the eyes were operated on and followed by one surgeon.

CRYSTALLINE LENS

Broendstrup, Poul. Amblyopia exanopsia in infantile cataract. *Acta Ophth.*, 1944, v. 22, pt. 1, pp. 52-71.

The author reviews the literature and gives a detailed analysis of his own material which comprises 29 cases of unilateral spontaneous cataract, congenital or acquired before the tenth year, and 48 cases of unilateral traumatic cataract acquired before the tenth year. The data show that amblyopia exanopsia vitiates the surgical result of operation for cataracts acquired in early childhood. Functional amblyopia in infantile cataract is very widespread, and is not influenced significantly by removal of the cataract; uncorrected aphakia does not counteract the amblyopia, and may accentuate it. The prognosis for visual acuity is therefore not influenced by early or late operation. Amblyopia exanopsia is apt to develop as a sequel to traumatic anopsia incurred before the eighth year of life. If the cataract appears after the eighth year of life functional amblyopia is not apt to develop.

Ray K. Daily.

Broendstrup, Poul. Operative results obtained in bilateral infantile cataract. *Acta Ophth.*, 1945, v. 23, pt. 2, pp. 175-194.

The literature is reviewed, and the author's material of 155 cases is subjected to a detailed analysis. The data show that bilateral infantile cataracts fall into two groups: stationary partial, and dense cataracts. There is danger of amblyopia exanopsia if partial cataracts are treated surgically too early. Infants with dense cataracts, if not operated upon early, will face the same fate as children born blind. Of 132 children with partial cataracts who were operated upon during their first school years 85 percent had a visual acuity of 6/18 or better during in the best eye. The best visual results were obtained in eyes in which good function could be determined preoperatively, and which were not operated upon too early. The results indicate that surgical intervention before the age of seven years may lead to irreversible amblyopia exanopsia.

There were 23 cases of bilateral congenital dense cataract. This type of cataract is frequently associated with other ocular anomalies that preclude good vision. Such eyes are apt to develop postoperative complications. A visual acuity of 6/36 is considered to be a good result. These patients should be operated upon at the age of one year, and should be given a refractive correction as soon as possible.

Ray K. Daily.

Broendstrup, Poul. The squinting position of weak-sighted eyes. *Acta Ophth.*, 1944, v. 22, pt. 4, pp. 386-393. (See Section 4, Ocular movements.)

Gilje, Kristian. Has saturation with ascorbic acid any influence upon hem-

orrhage after cataract operation? *Acta Ophth.*, 1945, v. 23, pt. 2, pp. 127-134.

The material of this study consists of 45 patients who were operated upon for cataract during March, April, and May, 1941. The patients were saturated with ascorbic acid before operation and for 10 days after. No effect on the incidence of post-operative hemorrhage could be ascertained. The author's findings therefore do not confirm Urbanek's contention that saturation with ascorbic acid protects against postoperative hyphema. Ray K. Daily.

Mihalyhegy, G. Foreign body injury of the lens. *Ophthalmologica*, 1945, v. 109, Feb.-March, pp. 159-163.

A glistening foreign body was found in the lens of a non-irritated eye of a soldier after an explosion. X-ray examination was negative. It was found that the foreign body was gun powder which is insoluble in the aqueous and the tissue of the lens and, therefore, did no chemical harm. As the tear in the lens capsule closed immediately after the injury, no traumatic cataract ensued and final vision was 6/7.

Max Hirschfelder.

Rivas Cherif, Manuel de. Anesthesia in the cataract operation. *Anales de la Soc. Mex. de Oft.*, etc., 1945, v. 20, July-Sept., pp. 93-102.

A general discussion of the varying practice of different authors regarding local anesthesia. W. H. Crisp.

Rocha, Martins. Concerning microphakia. *Arquivos do Instituto Penido Burnier*, 1945, v. 7, Dec., pp. 151-160.

The author records three cases, in a girl aged two years, and in two brothers aged respectively three and two years. Of the latter two patients the

parents were first cousins and had three children. The lenses were extracted, apparently with good result. (3 figures, references.) W. H. Crisp.

10

RETINA AND VITREOUS

Andersen, O. C. Three cases with remains of the hyaloid artery and anomalies of the retinal vessels. *Acta Ophth.*, 1944, v. 22, pt. 3, pp. 270-274.

The interesting feature of these cases is the inferior temporal direction of the vascular band, which is rare. In the first case there were also remains of the tunica vasculosa lentis on the posterior surface of the lens. The second case had two fibrous bands; in addition to the one coursing, through the vitreous, as is usual, there was another one situated on the surface of the retina. Such formations are very rare. In addition, these eyes also had anomalies of the fundus vessels. In the first patient there were no vessels in the fundus; in the second the arteries were very narrow and in the superior portion of the retina the vessels were scarce and thin. A similar fundus picture was seen in the third patient, except that the lower portion of the fundus was almost normal. The optic disc was pale in all of them and function was correspondingly reduced, no doubt because of the inadequate blood supply. Ray K. Daily.

Bangerter, A. Contribution to the diagnosis, differential diagnosis and therapy of cystoid edema of the macula (macular cysts). *Ophthalmologica*, 1945, v. 109, Feb.-March, pp. 102-122.

Macular cysts, the pathologic existence of which has been known for a long time, were first clinically recognized by Vogt who employed red-free ophthalmoscopy for their detection. He

described the clinical picture as "honey-comb macula". Whereas the usual ophthalmoscopic examination with white light reveals only the very advanced cystoid changes, it is possible to recognize very small and early cysts by slitlamp observation with use of the fundus contact glass. These small cysts are missed by any other method. The article describes in detail the slitlamp appearance of the cystoid macula and its differentiation from a hole in the macula and from the picture produced by degeneration due to sclerosis of the choroid. One group of Bangerter's patients with cystoid degeneration also showed senile choroidal sclerosis. It was in this group that a new treatment with retrobulbar injection of atropine sulfate (1 : 1000 solution, 0.3 to 0.6 c.c., two to four times per week for 12 injections) seemed effective. The author proposes this treatment with the idea that retrobulbar vasodilation improves the nutritional disturbance of the macular area which causes the formation of cysts. A second form of macular cysts was found in patients suffering from retinal detachment, branch thrombosis of retinal veins, retinitis pigmentosa, and inflammatory intraocular changes. These did not respond as regularly as those in the senile group to the treatment with retrobulbar injection of atropine. (Photographs, literature.) Max Hirschfelder.

Broendstrup, Poul. **Ablatio falciformis congenita**. *Acta Ophth.*, 1944, v. 22, pt. 2, pp. 193-202.

In 1936 Weve reported under this name eight cases of a familial congenital anomaly. The characteristic feature of the anomaly is a double retinal layer which extends as a sickle from the papilla to the region between the ciliary

body and the lens. The author reports the case of 4½-year-old girl who had this anomaly in the right eye, and a coloboma of the choroid in the left. (2 illustrations.) Ray K. Daily.

Brueckner, R., and Field, N. H. **Contribution to the complex of symptoms in chorioretinitis centralis serosa** (Kitahara). *Ophthalmologica*, 1945, v. 109, June, pp. 281-317.

Chorioretinitis centralis serosa is characterized by a sharply limited, flatly detached area in the macular region. The changes may be minute and the area has the form of a circle or of an ellipse. Numerous small yellowish spots are usually found in the area after three to five weeks. Their histologic significance is not clear. The visual acuity is somewhat diminished, there is alteration in the sense of color perception, micropsia, and metamorphopsia. The condition usually clears up after weeks or months with complete return of the visual acuity. The existing relative central scotoma disappears. However, recurrences are common. The authors observed three patients who had the typical complex of symptoms and findings. They believe that edema has an important part in the pathogenesis of the condition and that it arises in the choroid, whereas the retina becomes detached and invaded by the fluid secondarily. It must be assumed that there is a pathologic change in the permeability of the capillaries of the choroid. No definite cause has been found nor has therapy been successful. The relative scotoma was extensively studied by one of the patients and his drawings which accompany the article are correlated with the clinical findings. There were certain unusual color images and afterimages

within the scotomatous area that varied during the clinical course depending on the intensity of the pathologic changes. With diascleral transillumination a positive scotoma appeared in the entoptic image. During autofunduscopy by the patients a small light reflex that changed its position with the moving of the transilluminating lamp, was noted in the positive scotoma. The authors call it the "entoptic reflex of convex retinal surface" and discuss its theoretical basis. (3 color plates, drawings, references.)

Max Hirschfelder.

Brueckner, R. **A case of thrombosis of the central retinal vein after a trauma.** *Ophthalmologica*, 1945, v. 109, Apr.-May, pp. 203-211.

A typical thrombosis of the central retinal vein was found in an eye that had suffered two contusions a few weeks before. It was assumed that the sudden increase of pressure in the central retinal vein lead to tears in its intima and gave rise to the slow formation of a thrombus. Brueckner discusses the physical and physiologic aspects that lead him to believe that there was a connection between the contusion and the thrombosis. The state insurance service recognized his considerations as a basis for assuming liability.

Max Hirschfelder.

Cardello, G. **A case of retinal periphlebitis.** *Rassegna Ital. d'Ottal.* 1946, v. 15, no. 1 and 2., p. 56.

The patient described was a 23-year-old woman whose physical and laboratory tests were all negative, except for a strongly positive tuberculin reaction. The retinal changes observed were sheathing, constrictions, and dilatations of the veins of medium and smaller

caliber. Extensive hemorrhages were present but vision was 6/6. Tuberculin therapy was not feasible but recovery followed the use of calcium, arsenic, vitamin C, and auto-hemotherapy. Tuberculosis was the assumed cause. (4 figures.) Eugene M. Blake.

Colvin, Clifford. **Detachment of the retina.** *M. J. Australia*, 1946, v. 2, July 20, pp. 80-83.

The author discusses the etiology and pathology of retinal detachment. He recommends transillumination of all eyes. At operation the detached area of the retina is projected on to the sclera and marked with India ink. After the conjunctiva has been reflected, a spot of light from the ophthalmoscope is easily visible. A mark is made on the sclera 8.8 mm. from the limbus in the approximate meridian of the tear. Surface diathermy with the Larsson electrode is used. Case reports are included.

I. E. Gaynon.

Conte, W. R., McCammon, C. S., and Christie, A. **Congenital defects following maternal rubella.** *Am. J. Dis. Child.*, 1945, v. 70, Nov.-Dec. p. 301.

The authors questioned the mothers of 120 infants who were born with congenital abnormalities during a five year period ending 1944. Of this group, five mothers reported having had rubella, four of them in the first trimester of pregnancy. Four of the five infants had congenital cataracts. The incidence of rubella in these mothers was at least ten times that of the rubella morbidity in the female adult population generally. It is felt that this constitutes evidence that rubella in pregnancy is a predisposing cause of congenital defects.

The authors found, as have all pre-

vious investigators, that most of the mothers reporting rubella had the disease in the first trimester of pregnancy.

Benjamin Milder.

Gil, R. R., and Blaza, J. F. Retinal detachment in a pregnant woman. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Oct., p. 531.

A case of retinal detachment occurring in the third month of pregnancy is reported. The pregnancy was uncomplicated and the eyes were highly myopic. The detachment was not related to the pregnancy. The patient was operated on and several diathermic punctures made to seal the retinal tears. Recovery was uncomplicated and vision was considerably improved. The pregnancy progressed to term uneventfully. (Illustrations and bibliography.)

Plinio Montalván.

Gradle, H. S. Surgical treatment of retinal detachment. *Anales Argentinos de Oft.*, 1945, v. 6, Apr.-May-June, pp. 53-59.

The author feels that preoperative therapy is extremely important in achieving a satisfactory surgical result. For five to ten days the patient is immobilized in a position favoring approximation of the separated tissues, atropine is instilled, and the eyes are covered. Occasionally, even a satisfactory operation does not result in increased visual acuity, owing to macular degeneration or cyst formation. If the retinal tear is sealed, the chance for recovery is much enhanced, therefore, an intensive search for the site of a tear must be made. If a tear is not seen at first, it may appear at a later examination, after the patient has rested, because of a shift or absorption of sub-retinal fluid. The author prefers to use the electrodiathermy needle that he de-

scribed in 1935. He makes a complete puncture of the sclera with a current of fifty to seventy milliamperes. He observes the fundus during this procedure, between penetrations, to make certain that they are properly placed. The sub-retinal fluid must be drained to achieve a proper chorioretinal cicatrix. Occasionally some months may pass before a good adhesion occurs, because of slow absorption of the remaining sub-retinal fluid. He reports good anatomic results in 54 to 74 percent of his operations, and good functional results in only thirty-seven percent in the past six years. (2 illustrations.)

Edward Saskin.

Hertzberg, R. Quinine amaurosis. Report of a case. *M. J. Australia*, 1946, v. 2, July 20, pp. 92-93.

The patient noted that after taking 50 grains of quinine sulfate, his vision became blurred and on the third day he was unable to see at all. Atabrine was substituted for quinine and the next day vision began to return. The pupils were dilated and immobile, there was edema of the macula in each eye and the fields were normal. Two days later the discs became pale and the arteries attenuated. After two weeks the visual acuity became 6/6 and the pupillary reactions normal, although the vessels were still attenuated and the discs pale.

I. E. Gaynon.

Lijó Pavia, J., and Lachman, R. Macula. Small hole due to photo-traumatism. Considerations on two cases. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Oct., p. 496.

The authors report two cases of solar eclipse retinitis in which typical holes of the macula were observed. A small central scotoma with subnormal vision

remained after recovery. The literature on the subject is briefly discussed and the authors stress the traumatic action of light on the forvea when the luminous rays are converging on the macular region. The article is illustrated.

Plinio Montalván.

Lyle, D. J. Early ocular manifestations in the Laurence-Moon-Biedl syndrome. *Amer. Jour. Ophth.*, 1946, v. 29, pp. 939-945. (1 table, 3 figures, references.)

Johnson, H. C. Retinal venous sheathing in multiple sclerosis; report of a case. *Amer. Jour. Ophth.*, 1946, v. 29, Sept., pp. 1150-1151. (See section 17, Systemic diseases and parasites.)

Manschot, W. A. The fundus oculi in subarachnoid hemorrhage. *Acta Ophth.* 1944, v. 22, pt. 3, pp. 281-299.

The author reports three cases of subarachnoid hemorrhage accompanied by hemorrhages in the fundus of each eye. The eyeballs and optic nerves were examined microscopically, and Manschot finds in the microscopic picture an explanation for the extensive form which these hemorrhages assume in the retina, and which distinguishes them from the smaller retinal hemorrhages of different etiology. The anatomic data indicate that the hemorrhage is caused by a complete occlusion of the central retinal vein in the intervaginal space. The suddenness of the occlusion and the pressure within the optic nerve driving the venous blood in a retrograde direction creates such a high pressure within the retinal veins that they rupture and produce the large hemorrhages characteristic of subarachnoid hemorrhage. The smaller hemorrhages seen in thrombosis of the central retinal vein and in papilledema are formed by dia-

pedesis in a slowly developing stasis in the retinal veins, which rarely causes their rupture. (5 microphotographs.)

Ray K. Daily.

Nyquist, B. Two cases of retinitis as a complication in acute infections during chemotherapy. *Acta Ophth.*, 1943, v. 21, pt. 1-2, pp. 61-67.

One occurred in a patient whose erysipelas was treated with sulfanilamide. Blurring of vision occurred simultaneously with jaundice and exanthema after the patient ingested 7.5 gm. of the drug. The fundus had a small white spot up and temporally from the papilla. Recovery was complete, and treatment consisted in rest and dark glasses. The patient who had pneumonia, developed serious blurring of vision after taking 20 gm. of sulfathiazole in the course of five days. He had a bilateral central retinitis with large central scotomata. The exudates were gradually absorbed, and the final result was an absolute central scotoma one degree in diameter, and visual acuity of 5/35. (2 photographs.)

Ray K. Daily.

Nano, J. M., and Cuille, E. Obstruction of the central artery of the retina not affecting the macular area. *La Semana Med.*, 1946, May 9, 53d yr. p. 835.

The macular area had escaped, as usual, on account of the existence of cilioretinal vessels. Retinal photographs show the contrast between the normal color of the preserved macular area and the pale edematous appearance of the rest of the fundus. The central vision of the other eye was two thirds, that of the involved eye one half. There are also a fundus drawing and two visual fields. (References.)

PAN-AMERICAN NOTES

Edited by DR. M. URIBE TRONCOSO
500 West End Avenue, New York 24

Communications should reach the editor by the 12th of the month

SOCIETIES

The Sociedade de Oftalmologia de São Paulo has elected the following officers to serve during the fiscal year 1946: President, Dr. Armando Gallo; Vice President, Dr. Jose Mendonça de Barros; General Secretary, Dr. Amedée Peret; Secretary, Dr. Paulo Aranha; Treasurer, Dr. Aureliano Fonseca.

The prize offered annually by the Sociedade de Oftalmologia de São Paulo was won this year by Dr. José de Freitas, graduate of the University of Minas Geraes. This prize was offered to doctors who, having graduated the year before from a recognized medical school, wish to specialize in ophthalmology. It is awarded on the merits of a 10-minute dissertation on one of 20 subjects which have previously been studied by the candidate, one of these being drawn by lot on the night of the prize giving.

During the month of December, 1945, Prof. Edmond Velter, the well-known French ophthalmologist, visited São Paulo. Prof. Velter read a paper at a meeting of the Sociedade de Oftalmologia de São Paulo, and the São Paulo ophthalmologists gave a dinner for him at which Dr. Pereira Gomes made a speech of welcome on behalf of his colleagues. Prof. Velter, accompanied by Dr. Herdocia, of Costa Rica, and Dr. Cintra Gordinho, of São Paulo, then left for Campinas where they visited the ophthalmologic services and were given the opportunity of visiting a coffee "fazenda" in which they were greatly interested.

The Fifth Brazilian Congress of Ophthalmology is scheduled to convene in Salvador, Bahia, from June 28 to July 2, 1947. The following papers are included in the program: "Vision of Vehicle Drivers," by Dr. Pereira Gomes, São Paulo; "Abiotrophic Diseases of the Macula," by Dr. Carlos Damel, Buenos Aires; "Vitamins in Ophthalmology," by Dr. Joviano de Rezende, Rio de Janeiro; (this paper will be discussed by Dr. Geraldo Queiroga, Belo Horizonte, and Dr. Heitor Marback, Bahia; "Glaucoma," by Dr. Renato de Toledo, São Paulo; (this paper will be discussed by Dr. Jacques Tupinambá, São Paulo, and Dr. Ruy Rolim, Rio de Janeiro. Surgical demonstrations will also be given during the meeting. The local committee has arranged a program of excursions

and visits to places of interest in Salvador.

Dr. Saul Fontoura has been elected President of the Sociedade de Oftalmologia e Otrrinolaringologia do Rio Grande do Sul for 1946.

The Sociedad Cubana de Oftalmología has elected the following officers who will serve until January 1948: President, Dr. Lorenzo Comas; Vice Presidents, Dr. Rodolfo Hernández and Dr. Miguel Mery; Treasurer, Dr. Candido Durán; Secretary, Dr. Oscar Horstmann, and Vice Secretary, Dr. Tomas R. Yanes. At its first meeting in 1946 the Society agreed to hold the First National Congress of Ophthalmology in January 1947, with a symposium on the surgical treatment of cataract.

The first Congress of Medicine in Mexico was held in Mexico City from August 4 to 10, 1946. Although the Mexican Medical Association had held meetings since 1931, the association was transformed into a medical syndicate and, during the war, meetings were suspended. This first postwar Congress was held under the auspices of the Medical Society of the General Hospital and was very well attended. Important papers were read in the sections of Medicine, Hematology, Micro-Biology, Parasitology, Pathology, and Allergy.

The first Pan-American Congress of Otorhino-Laryngology and Broncho-Esophagology was held at the Palmer House, on October 17, 18 and 19, 1946. It was sponsored by the American Academy of Ophthalmology and Otolaryngology. The Latin-American participants were invited to attend the meeting of the American Academy which opened on Sunday, October 15th. The inaugural session of the Pan-American Congress took place on the night of October 17th with a Pan-American dinner, and the first scientific meeting was held jointly with the final session of the Academy on the morning of October 18th.

The Sociedad Cubana de Oftalmologia has started work on the organization of the third Pan-American Congress of Ophthalmology which is scheduled to convene in Havana in February, 1948. The Cuban government will provide all the necessary facilities and sponsor the event, as the importance of this meeting is well recognized by all.

MISCELLANEOUS

The second number for 1945 of the publication, *Estudios de Informaciones Oftalmológicas* contains the following articles: B. Perpiña Robert, "Blue Sclerotics"; I. Barraquer, "Sclerocorneal Suture in Cataract Operations"; J. Barraquer Moner, "New Method of Corneal Section in Total Extraction of Cataract"; R. Almeida Ribeiro, "Congenital Cataracts and Phacolysis." These papers are illustrated with beautiful figures.

PERSONALS

Dr. A. Moreu. *El Problema del Glaucoma Verum* (The Problem of Glaucoma Verum): The distinguished Spanish ophthalmologist, Dr. Moreu, of Valencia, has just published an interesting book of 336 pages with numerous illustrations dealing with ocular tension, primary and secondary glaucoma and their treatment, both medical and surgical. Although a review of this book is forthcoming, we want to point it out to all those ophthalmologists who speak Spanish.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. Mary Buchanan, Philadelphia, Pennsylvania, died August 8, 1946, aged 76 years.

Dr. Thomas Edward Carmody, Denver, Colorado, died August 27, 1946, aged 71 years.

Dr. Robert K. Lambert, New York, New York, died October 3, 1946, aged 47 years.

Dr. Richard Joseph Tivnen, Chicago, Illinois, died August 27, 1946, aged 71 years.

MISCELLANEOUS

The Division of Ophthalmology of the University of California announces the receipt of a gift of \$20,000 donated by Mrs. Francis I. Proctor for the establishment of a yearly lecture in ophthalmology in memory of her husband. The first Francis I. Proctor Lecture will be given on Friday, December 20th, at the University of California Medical School in San Francisco by Dr. Kenneth Swan of the University of Oregon. His subject will be "Some Contemporary Concepts of Pharmacology and Toxicology of the Cornea." The lecture is open to all ophthalmologists.

Dr. Francis I. Proctor was born in Boston in 1864. After his preliminary education, he attended and was graduated from the Harvard University Medical School in 1892. Following graduation, he went into the specialty of ophthalmology and eventually became Chief Surgeon of the Massachusetts Eye and Ear Infirmary.

On retirement he settled in Santa Fe, New Mexico, and became consultant in ophthalmology to the Office of Indian Affairs. While here, he became interested in trachoma, and it was he who induced Noguchi to make his studies in trachoma. When Thygeson was unable to con-

firm Noguchi's work, Dr. Proctor went to Denver to interview Thygeson and this established a friendship that lasted until his death. After Noguchi's death, it was Dr. Proctor who stimulated and participated in the work that was eventually to establish a filterable virus as the causative agent of trachoma. In addition, it was Dr. Proctor's generosity and determination that made possible the final confirmation of the etiology of trachoma. While Dr. Proctor did very little of the original work on trachoma, he traveled the world over to interview personally all who were doing outstanding work in the field, and it was his enthusiasm and encouragement that made possible the final solving of this problem.

It was Dr. Proctor's interest in furthering ophthalmology in the western part of the United States that resulted in the establishment of this lecture on the Pacific Coast. It is the plan of the Division of Ophthalmology to have one of the outstanding figures in the field of ophthalmology deliver the lecture each year.

The Ophthalmological Study Council opened its second course at the Hotel Soreno, St. Petersburg, Florida, on November 2nd. The course will continue through January 15th. Included among those presenting the basic subjects in the field of ophthalmology are:

Dr. Joseph Igersheimer, Boston, November 4-12, Sensory Neuro-Ophthalmology perimetry.
Dr. Herman Burian, Boston, November 13-23, Motor Neuro-Ophthalmology.

Dr. Georgiana Theobald, Oak Park, Illinois, November 25-30, General Pathology and Special Pathology.

Drs. Everett Goar, Dallas; Milton Berliner, New York; Robert Masters, Indianapolis; and Harvey E. Thorpe, Pittsburgh, December 2-7, Slitlamp Biomicroscopy.

Dr. Placidus J. Leinfelder, Iowa City, December 9-11, Practical Perimetry in Sections.

Dr. Algernon Reese, New York, December 12-14, Pathology—Tumors.

Dr. Cecil O'Brien, Iowa City, December 16-21, Surgical Principles, Pathology, Retina, Choroid and Optic Nerve and Ophthalmoscopy.

Drs. Walter B. Lancaster, Boston; Paul Boeder, Southbridge, Massachusetts; and Arthur Linksz, New York, November 4-16, Optics, Visual Physiology.

Drs. S. Judd Beach, Portland, Maine; James J. Regan, Boston; and W. B. Lancaster, Boston, November 18-27, Refraction Theory and Practice.

Dr. Trygve Gunderson, Boston, November 28-December 5, Pathology of Cornea and External Diseases.

Dr. Phillips Thygeson, San Jose, California, December 6-14, Bacteriology.

Dr. Albert N. Lemoine, Jr., Kansas City, Missouri, December 16, Anatomy, Histology, Embryology, Heredity.

Dr. Peter Kronfeld, Chicago, January 1-9, Pharmacology.

Dr. Paul Chandler, Boston, January 10-13, Glaucoma.

V. Everett Kinsey, Ph.D., Boston, January 1-9, Biochemistry.

Dr. Henry Wagener, Rochester, Minnesota, January 10-15, Medical Ophthalmology and Ophthalmoscopy.

Additional information may be obtained from Dr. Walter B. Lancaster, 520 Commonwealth Avenue, Boston.

An eye clinic on wheels was dedicated in special ceremonies at Trenton, New Jersey, October 12. The unit is said to be the first mobile clinic for providing eye care in remote areas in the country. Nineteen feet long and more than 6 feet wide, the unit contains a refracting chair, refractor, slitlamp, retinoscopes, and ophthalmoscopes. Diagnosis of eye diseases, minor treatments and operations, along with examination of eyes for glasses can now be made readily available in all areas. The new eye clinic is similar to the mobile optical units used overseas by the armed forces.

The Department of Ophthalmology, University of Toronto, has undertaken post-graduate training during the past year. This has been aided by a generous annual grant from Mr. Percy Hermant for establishing Fellowships in Ophthalmology. The post-graduate training is now three years for the Fellows. The first

year's work is in the basic sciences of Ophthalmology, and the final two years are spent in clinical internships in one of the Toronto hospitals. Dr. J. R. Gaby, Toronto, and Dr. A. W. Mahood, Vancouver, have been appointed Fellows for the current year. In addition to the Fellows, there are a number of two-year clinical internships in Ophthalmology.

The graduate instruction in Ophthalmology in the hospitals in Toronto has been coordinated under the direction of the University. Didactic lectures are presented weekly from October until May to the internes by the members of the teaching staff in Ophthalmology. On Saturday mornings, ward rounds are made at the Toronto General Hospital and are attended by the internes in Ophthalmology from the various hospitals.

The internes are rotated through the Department of Ophthalmology of the Hospital for Sick Children in order that they may become familiar with the medical and surgical procedures of children's Ophthalmology.

The senior internes are given instruction in the preparation and presentation of scientific papers, and each one presents a paper at the Toronto Academy of Medicine, Section of Ophthalmology.

There have been a number of changes in the teaching staff in the University Eye Department. Dr. Walter W. Wright has retired as Professor of Ophthalmology in the University and Head of Ophthalmology in the Toronto General Hospital. He has been appointed Professor Emeritus. Dr. A. J. Elliot succeeds Dr. Wright. Dr. A. E. MacDonald and Dr. A. Lloyd Morgan have been made Assistant Professors of Ophthalmology and the teaching staff of the university department has been increased by the appointments of Dr. J. S. Crawford, Dr. C. E. McCulloch, Dr. J. C. Hill, and Dr. M. E. Albertson.

The George Washington University Department of Ophthalmology is planning the resumption of the intensive post-graduate courses in Ophthalmology, the next course to be given the week of February 3 to 8, 1947. These courses were discontinued during the war. The following guest lecturers are assisting the resident staff on the program: Dr. F. Heed Adler, Philadelphia; Dr. J. Mason Baird, Atlanta; Dr. S. Judd Beach, Portland, Maine; Dr. Herman M. Burian, Boston; Dr. Ramon Castroviejo, New York; Dr. C. Alvin Clapp, Baltimore; Dr. F. Bruce Fraclick, Ann Arbor, Michigan; Dr. Deane B. Judd, Washington, D.C.; Dr. Peter C. Kronfeld, Chicago; Dr. Walter I. Lillie, Philadelphia; Dr. Angus L. MacLean, Baltimore; Mr. Philip L. Salvatori, New York; Dr. Harold G. Scheie, Philadelphia;

Dr. Edmund B. Spaeth, Philadelphia; Dr. Frederick W. Stocker, Durham, North Carolina.

The 10th annual post-graduate course in ocular surgery, pathology, and orthoptics will be given during the week of January 27-February 1, 1947. This is a practical course and limited to 30 participants.

For further details write to the Secretary, Mary Everist Kramer, Suite 34, 1801 K Street N.W., Washington 6, D.C.

Plans for a new \$4,500,000, 10-story clinic hospital for the 126-year-old New York Eye and Ear Infirmary are outlined by Dr. Conrad Berens, superintendent, at the annual meeting of the infirmary's former internes, attended by 100 physicians at the University Club, 1 West 54th Street.

The hospital will adjoin the proposed New York University-Bellevue Medical Center between 30th and 34th streets on East River Drive, he said. He forecast completion in three to five years.

Amalgamated since February with the New York University-Bellevue Medical School, the infirmary has begun joint teaching and research activities with the school.

Dr. Currier McEwen, Dean of the New York University-Bellevue Medical School, told the alumni that identities of the two amalgamated institutions would be kept separate, although both would gain by their affiliation.

The opening address of the program was given by Dr. Conrad Berens. Mr. Hugh E. Paine, treasurer of the Board of Directors spoke on: "Mission of Trustees in Furthering Association of the Infirmary and New York University." Dr. Edward H. Cary, speaker of the evening, talked on: "Future Plans of the New York Eye and Ear Infirmary." Other guest speakers were: Dr. Daniel B. Kirby, Dr. J. Morrisset Smith, Dr. Joseph Kelly, Dr. Clyde E. McDannald, Dr. Bernard Samuels, and Dr. Edgar Burchell.

SOCIETIES

On Thursday, November 21st, Dr. Algernon B. Reese of New York delivered the ninth annual deSchweinitz Lecture at a meeting of the Section on Ophthalmology, College of Physicians of Philadelphia. Dr. Reese's subject was "Pigmented Tumors."

The Milwaukee Oto-Ophthalmic Society met on October 22nd at the Milwaukee Athletic Club. The program included a talk by Dr. Edward Waldeck on "Pulsating Exophthalmos—Presentation of a Case"; and a paper by Dr. Walter Reinking (by invitation) on "Practice of Otolaryngology in Mexico City."

Among the many interesting topics on the program of the 1946 conference of the National Society for the Prevention of Blindness, Inc., held at the Hotel Pennsylvania, New York, November 25th, 26th, and 27th were:

THE VISION PROGRAM IN INDUSTRY

Chairman: THOMAS D. ALLEN, M.D., Chicago, Member, Joint Committee on Occupational Ophthalmology, American Academy of Ophthalmology and Otolaryngology and American Medical Association.
